# What Drives Repo Haircuts?

## Evidence from the UK Market\*

### Abstract

Using a unique transaction-level dataset covering the UK bilateral repo market, we show that only 61% of the repos are backed by high-quality collateral, with banks intermediating liquidity across counterparties and using CCPs mainly for high-quality collateral and netting benefits. Haircuts reflect both collateral and borrower characteristics: larger, higher-rated, less levered, less sophisticated borrowers, and those with repeated relationships receive lower or even zero haircuts. Borrower attributes explain as much variation in haircuts as collateral quality, while lender liquidity and default risk play little role. We also document a pecking order in collateral use, with higher-quality assets pledged first.

*Keywords:* repurchase agreement, systemic risk, repo market, margin, haircut.

The repurchase agreement (repo) market is a major tool for short-term funding of financial institutions and a potential source of systemic risk. Yet, because repo transactions are over-the-counter, contract terms are rarely disclosed, except for U.S. tri-party repos backed by Treasuries. Existing studies on bilateral repos—where settlement is on a delivery-versus-payment basis—are scarce, and typically limited either by the absence of counterparty information or by narrow coverage. Moreover, despite the fact that EU and UK repo markets are larger than those in the U.S., our understanding of repo contract terms continues to rely heavily on U.S. data. As a result, we know little about the patterns of bilateral deals or the cross-sectional relationships between haircuts, collateral, and counterparty characteristics in European markets. We fill this gap.

We use a unique transaction-level dataset from the UK bilateral repo market, covering about 24% of total activity and spanning a wide cross-section of borrowers and lenders. The dataset features heterogeneous collateral, counterparties, and haircut levels ranging from zero to over 45%. This richness allows us to provide a market-wide view of how banks intermediate liquidity and how haircut levels are shaped by collateral, contract terms, and counterparty characteristics.<sup>1</sup>

We find that deal-level intrinsic risk characteristics increase haircuts: longer maturity contracts, as well as collateral with higher (market and default) risk measures, demand higher haircuts. While it is reassuring that low quality or illiquid collateral is associated with higher haircut, theories on leverage and collateralized debt also suggest a first order role for counterparty characteristics that has largely not been documented in empirical studies. Remarkably, we find that the identity of the borrower, its riskiness and level of sophistication, as well as repeated interactions with the lender, are key determinants of haircuts. Overall, borrower characteristics have *larger* effects on haircuts than asset characteristics, whereas lender characteristics—except collateral concentration—do not appear to be primary drivers. That is, the importance of counterparty characteristics for haircut is first order in the bilateral repo market with heterogeneous collateral and market participants. Additionally, netting benefits appear to be a first order driver of repo transactions with CCPs (that are overall characterized by higher quality collateral). Furthermore, we observe a pecking order of collateral choice by borrowers, with higher quality securities more likely to be posted first.

Our bird’s-eye investigation reveals four distinct features about the UK bilateral repo

---

<sup>1</sup>The Office of Financial Research (OFR) has started to collect such data for the U.S. and Hempel et al. (2023) describe the pilot data collection of non-centrally cleared bilateral repurchase agreement spanning nine dealers across three reporting dates. In the EU, the Money Market Statistical Reporting (MMSR) collects all repo transactions made by 38 dealer banks. Focusing on repos backed by government collateral, Eisenschmidt et al. (2024) studies the monetary policy transmission in this market segment.

market. First, we find that only 61% of collateral used in the UK market can be categorized as high-quality collateral—government securities rated AA and above. Among the 39% of the riskier collateral, 7% are non-government securities such as corporate bonds, securitized products and others. In contrast, the existing studies using tri-party repo data in the U.S. market find that high-quality securities such as U.S. Treasuries are predominantly used as collateral (e.g., Copeland et al. (2010), Baklanova et al. (2019)).<sup>2</sup> The cross-sectional variation in the qualities of collateral used in the bilateral repo transactions leads to significant heterogeneity in haircuts among repo contracts in the UK market (from as low as 0 to as high as 45%).

Second, we find a clear pattern on how banks intermediate liquidity using central clearing counterparties (CCPs), and from asset managers to hedge funds via the UK bilateral repo market. Banks obtain liquidity from asset managers, while providing liquidity to hedge funds. In doing so, banks also earn intermediating spreads as they charge higher haircuts to their (net) borrowers—hedge funds—and are charged less by their (net) lenders—asset managers. For example, the banks charge intermediation spreads in terms of haircut as high as 1.3% to hedge funds and as low as 30 bps to broker dealers.<sup>3</sup> We also find that CCP trades are significantly different from non-CCP trades: banks tend to use high-quality collateral and to trade in large notional values when transacting with CCPs, and netting benefits are a key driver of CCP transactions.

Third, we find evidence for collateral rehypothecation. For government securities rated AA and above, the rehypothecation rate ranges from 26.3% for government bonds with maturity of 20 years and longer to 61.6% for government bonds with maturity from 10 to 20 years. This rate is much lower for non-government securities: which is 8.9% for bonds with maturity of 20 years or more and 27.7% for bonds with maturity of five years or less.

Fourth, we find that a significant portion of bilateral contracts have zero haircut—about 35% of all transactions—with relationship lending being their key driver.

After revealing these unique characteristics of the UK repo market in allocating liquidity, we turn to investigating the drivers behind the cross-sectional heterogeneity in haircuts, including the probability of receiving a zero haircut.

---

<sup>2</sup>The EU and UK repo markets have a larger share of lower-quality securities than the U.S. market for several reasons. First, the supply of high-quality government bonds is relatively low. For example, Germany is one of the main suppliers for safe assets in the euro area. The government debt-to-GDP ratio is much lower for Germany than the U.S., implying that the supply of the safest asset is relatively limited. Second, ECB accepts euro area government bonds of lower quality in their repo operations, albeit with higher haircuts. Hence, banks might have incentives to hold low-quality government bonds which offer access to central bank liquidity.

<sup>3</sup>We do not find that our reporting banks intermediate funds when trading with central banks and government agencies, insurance companies and pension funds, and other reporting banks. In fact, they often pay higher haircuts when borrowing from these counterparties.

In particular, we develop six testable hypotheses motivated by the existing theoretical work on collateralized borrowing and repo runs. Our six hypotheses can be broadly categorized into three groups: collateral, borrowers', and lenders' characteristics. Characteristics include typical quality variables such as default probability and credit rating but also liquidity indicators, concentration risks, counterparty types and some other variables. Existing theoretical models based on various market frictions have different predictions on how these characteristics affect haircuts.

To test our six hypotheses in the empirical investigation, we group the potential explanatory variables into five categories: deal, collateral, counterparty type, counterparty characteristics, and miscellaneous factors including concentration measures. We then examine their impact on the magnitude of haircuts and the probability of zero haircuts (given the large number of contracts with zero haircuts in the data). In the main analysis of the paper, we focus on the non-CCP subsample because the institutional setups are different when repo trades are cleared via CCPs. The reported haircuts by borrowers tend to be lower because they establish separate margin accounts with CCPs. Our regression analysis exploits heterogeneity in collateral and counterparty characteristics, yielding the following main results.

First, we find that transaction maturity – a deal characteristic – has a first order effect: haircuts are larger for longer maturities of the contract, with a one standard deviation increase in lending (borrowing) maturity being associated with a 5.4% (3.5%) increase in haircuts on average. Similarly, moving from a rating of AA or higher to a lower credit rating increases the average haircut at which the reporting banks lend from 4.14% to 9.52% (and from 1.25% to 1.83% when borrowing), with the marginal effect of a one-notch increase in rating of about -1.2%. Haircuts are also increasing in the Value at Risk (VaR) of the collateral (by about 0.5-1% per standard deviation) and in collateral concentration (by about 50-70bp per standard deviation). Moreover, haircuts are also generally lower for portfolios that include a safe asset (by about 60bp in reverse repo transactions). Focusing on reverse repos, i.e. contracts in which our reporting banks are lenders, adding collateral characteristics (in addition to the notional and maturity of the contract as well as currency, bank, and relationship fixed effects), increases the adjusted  $R^2$  by about 6.7%, stressing the saliency of these features of the contract. Furthermore, longer maturity collateral with ratings of AA or higher get rehypothecated twice as often as lower-rated ones.

Second, we find that counterparties matter in haircut determination. Strikingly, adding those covariates (in the reverse repo case) increases explanatory power by as much as the collateral characteristics (by about 6.3% in adjusted  $R^2$ ). In particular, on average, more sophisticated borrowers are charged 2.4–3.5% higher haircuts, or as much as 7.2% higher in the case of hedge funds. The latter are charged significantly higher haircuts, especially

when using non-government collateral: the haircut increases by a staggering 25%–28% when hedge funds borrow using such collateral. Moreover, larger borrowers with higher ratings receive lower haircuts, which shows that there is significant tiering in the repo market. A one standard deviation increase in borrower size decreases haircuts by 15.8%, while a similar decrease in leverage is associated with a reduction of 7.7%, and a one-notch increase in their rating reduces the haircut by about 1.7% *ceteris paribus*. We also find that borrower-lender relationships affect haircuts significantly: some borrowers receive consistently lower haircuts when interacting with certain counterparties, and one–two banks in our sample account for the bulk of repo trades with zero haircuts. Furthermore, the overwhelming majority of borrower-lender fixed effects yield statistically significant negative haircuts. That is, overall, larger, better rated, less levered, and less sophisticated borrowers, as well as borrowers with repeated interactions, get charged much lower haircuts, while more risky and sophisticated borrowers pay significantly larger ones.

Third, we find little evidence that lenders' liquidity position or default probabilities affect haircuts, suggesting that the traditional bank run mechanism cannot explain repo runs. This lends support to the alternative intertemporal feedback/coordination explanations of repo runs instead.

Fourth, when examining the likelihood of receiving zero haircuts, we find that, in addition to the determinants mentioned above, bilateral relationships explain a large part of the variation in the probability of receiving a zero haircut. This finding indicates that banks filter out repo clients in conducting repo business and give preferential haircuts to certain counterparties.

Fifth, we examine the CCP subsample of our database departing from the main part of the paper. It is still interesting to examine why banks clear certain repo trades through CCPs, and whether the haircuts charged by repo lenders to CCP are any different to non-CCP borrowers, since the existing understanding on CCP repo trades is limited. We find that banks earn a smaller average intermediation spread (in terms of haircuts) through CCPs than through non-CCP counterparties. That is, banks' lending (reverse repo) trades have lower haircuts when transacting with CCPs, whereas their borrowing (repo) trades have higher haircuts, reducing the average intermediation spread for our banks from 5.7% to 2.7%. Furthermore, trades in which banks lend to a CCP have a higher percentage of zero haircuts and the net position of banks with CCPs is close to zero (on average). Given that bank-CCP trades often involve high-quality collateral and have large notional values, this indicates that banks' repo transactions with CCPs might be motivated by netting benefits.

We investigate this further by computing a proxy variable capturing bilateral netting opportunities between our reporting banks and each of their counterparties. We find that

this proxy variable is significantly larger when CCPs act as counterparties. Furthermore, we find that netting benefits seem to be one of the main drivers of CCP trades in that the probability of a trade with a CCP increases by 40–43% when full netting can be achieved.

Sixth, we find that counterparties of our reporting banks seem to choose high-quality collateral first when borrowing via repo contracts, yielding a pecking order effect. That is, for a given maturity date of repo contracts, collateral posted first tend to be of higher quality.

Last but not least, we examine if there are any substitution effects between repo rates and haircuts by using a complementary dataset which contains information on both contract terms. We find strong evidence that, once deal and counterparty characteristics are accounted for, repo rate is irrelevant in explaining haircuts, suggesting that haircuts and repo rates have different drivers. This finding is in line with the evidence in the existing literature. For example, Eisenschmidt et al. (2024) (see table 3 therein) find no statistical association between rates and haircuts in the Money Market Statistical Reporting (MMSR) European repo dataset from the ECB.

**Closely related literature.** Theoretical research on repos emphasizes collateral constraints and the risk of runs. One strand focuses on differences of opinion in general equilibrium models, showing how belief dispersion affects leverage and haircuts (Geanakoplos (1997), Geanakoplos and Zame (2002), Geanakoplos (2003), Fostel and Geanakoplos (2012), Simsek (2013)). Another highlights contractual and informational frictions such as moral hazard, adverse selection, and sequential trade (Holmstrom and Tirole (1997); Dang et al. (2013), Dang et al. (2011), Gottardi, Maurin, and Monnet (2019); Biais, Heider, and Hoerova 2016). These frameworks imply that both collateral risk and counterparty characteristics can shape repo terms. Building on Diamond and Dybvig (1983), a related strand models repo runs as coordination failures, emphasizing rollover risk, endogenous information acquisition, or intertemporal feedback between collateral values and lending decisions (Acharya, Gale, and Yorulmazer (2011); Martin, Skeie, and Von Thadden (2014), Gorton and Odonez (2014), Ozdenoren, Yuan, and Zhang (2023)).

Empirical evidence has concentrated mainly on the U.S., particularly the tri-party market. Studies of the 2008–09 financial crisis show that bilateral repo haircuts rose sharply, triggering deleveraging by broker-dealers and contributing to hedge fund failures (Gorton and Metrick (2012), Adrian and Shin (2010), Adrian, Begalle, Copeland, and Martin (2013)). By contrast, tri-party haircuts remained largely unchanged, though funding was withdrawn from distressed institutions such as Bear Stearns and Lehman Brothers (Copeland, Martin, and Walker (2010), Krishnamurthy, Nagel, and Orlov (2014)). These differences have been linked to market microstructure: tri-party haircuts are fixed in custodial agreements, while

bilateral contracts adjust flexibly (Martin et al. (2014)). Other U.S. studies highlight segmentation, collateral concentration, and the role of relationships (Copeland et al. (2010); Hu, Pan, and Wang (2021); Weymuller 2013). However, data limitations are significant. Gorton and Metrick (2012) use a dealer-level dataset without counterparty detail; Auh and Landoni (2022) examine repos from one hedge fund family; and Baklanova, Caglio, Cipriani, and Copeland (2019) rely on three snapshots from nine bank holding companies. These restrictions make it difficult to assess how borrower characteristics influence haircuts.

European studies have largely focused on general collateral repos or transactions cleared through CCPs. Work on the euro area repo market emphasizes regulation and market structure (Mancini, Ranaldo, and Wrampelmeyer (2016), Boissel, Derrien, Ors, and Thesmar (2017), Corradin and Maddaloni (2020)). More recent papers examine the role of safe assets and collateral reuse (Aggarwal, Bai, and Laeven (2021), Jank, Moench, and Schneider (2021)). Compared to the U.S., European evidence on bilateral repos remains scarce, especially for transactions backed by riskier collateral.

Our paper contributes by studying the UK bilateral repo market with a uniquely rich dataset. Covering about 24% of total market activity, it includes transaction-level haircuts, collateral spanning a wide risk spectrum, and detailed counterparty characteristics. To our knowledge, this is the first European study to systematically test how both collateral and counterparty attributes shape haircut determination, thereby complementing the U.S.-focused and CCP-based evidence in the existing literature.

The rest of the paper is organized as follows. In Section 1 we provide a brief description of repurchase agreements. Section 2 outlines the main hypotheses that we test in the data. Section 3 describes the data. Section 4 analyzes the determinants of haircuts and presents the results for the six hypotheses. Section 5 concludes.

## 1 Background Information on Repurchase Agreements

A repurchase agreement is the simultaneous sale of securities and forward agreement to repurchase them at a specific price on a future date (Duffie, 1996). In effect, a repo is a collateralized loan where the underlying security serves as collateral. The party that borrows cash and delivers collateral is said to be doing a repo, while the party that lends cash and receives collateral is doing a reverse repo.<sup>4</sup>

---

<sup>4</sup>The repo rate is determined by the difference between the original loan value and the repayment amount. The haircut, or margin, is determined by the difference between the loan amount and the collateral value (Krishnamurthy et al., 2014). For example, if a borrower receives \$98 against \$100 worth of collateral, the haircut is 2%. In Europe, legal title to the collateral is transferred to the cash lender through an outright sale.

Repurchase agreements are broadly classified into two categories. Tri-party repo is a transaction in which post-trade services such as collateral management (e.g., selection, valuation, and verification of eligibility criteria), payments, and margining are outsourced to a third-party agent, typically a custodian bank.<sup>5</sup> A tri-party agent settles the repos on its books, and most existing repo studies focus on tri-party repos. In contrast, bilateral repos typically settle on a delivery-versus-payment basis, requiring the cash lender to have back-office capabilities to receive and manage the collateral (Adrian et al., 2013). Our dataset reflects this second category of repo contracts.

An interesting feature of the repo/reverse repo market is that central counterparties (CCPs) are beginning to clear a growing number of repos. CCPs position themselves between the two sides of a trade, creating a less complex network of exposures (Rehlon and Nixon, 2013). They provide benefits such as multilateral netting and facilities to manage member defaults in an orderly manner, but can also pose systemic risks to the financial system. CCPs always impose a haircut in the form of initial margin, whether in a reverse repo or repo.<sup>6</sup> Therefore, banks conducting reverse repo transactions with a CCP must provide a haircut, which amounts to a negative value for the haircut. Our dataset covers CCP trades with the reporting banks, offering an opportunity to examine the characteristics and assess the benefits of these trades.

## 2 Testable Hypotheses on Haircuts

We now develop the hypotheses on haircut determination that guide our empirical analysis. A first strand of the literature asks why borrowers raise funding through collateralized repos rather than outright sales of securities. The answer lies in market frictions: contract terms such as haircuts are designed to mitigate asymmetric information, moral hazard, or limits to pledgeability (Geanakoplos (2003), Simsek (2013), Dang et al. (2013), Dang et al. (2011), Ozdenoren et al. (2023), and Gottardi et al. (2019)). In Appendix A.1 we present a stylised model illustrating how information frictions motivate collateralized borrowing with repurchase.

A second strand emphasizes the use of repos to finance leveraged investment. Building

---

In the U.S., this is not the case, but repo collateral is not subject to automatic stay and can be sold by the lender if the borrower defaults (International Capital Market Association, 2019).

<sup>5</sup>There are two tri-party agents in the U.S.: Bank of New York Mellon and JPMorgan. In Europe, the main tri-party agents are Clearstream, Euroclear, Bank of New York Mellon, JPMorgan, and SegaInterSettle.

<sup>6</sup>When the collateral is a portfolio of assets, the haircut may be imposed on a subset of them to meet the initial margin requirement. Counterparties to CCPs also need to meet variation margin requirements. Since CCPs are purely intermediaries, these variation margins are passed through between lenders and borrowers.

on Holmstrom and Tirole (1997) and Adrian and Shin (2010), this literature also treats limited pledgeability as a consequence of informational frictions. For example, in Holmstrom and Tirole (1997) haircuts (equivalently, leverage constraints) are determined by the extent of moral hazard.

To disentangle the different economic mechanisms, we start with a stylized description of a repo-financed versus a straightforward asset purchase aiming to encapsulate the drivers for haircuts in the existing theories.<sup>7</sup> In a straightforward asset purchase, the risk-neutral borrower is willing to pay

$$\frac{\mathbb{E}[\delta_i]}{1 + R_{borrower}} \quad (1)$$

where  $\delta_i$  is next period random security payoff, which in practice should include all future cash flows such as dividend, interest and resale value for the repo contract indexed by  $i$ .

Alternatively, the risk-neutral borrower could finance the asset purchase using a repo loan. We denote the repo rate as  $R_{repo}$ , which is the cost of funding to the lender and the borrower's opportunity cost is  $R_{borrower}$ . It is intuitive that  $R_{repo} < R_{borrower}$  since the cost of funding is typically lower for the lender than for the borrowers. There has to be a cost  $c$  for entering the repo loan such that there is no arbitrage between these two ways of asset purchases. Furthermore, for illustrative purposes, let us assume that the lender is infinitely risk-averse and hence the maximum lending for a given security is the lowest possible recovery value of the repo contract. This, in turn, is modeled as being driven by two elements. First, suppose that there is a minimum possible payoff from the asset, denoted  $\delta_i^{min}$ . Second, the borrower can credibly pledge only a fraction  $\lambda_i \in (0, 1]$  of the asset payoff in a repo contract (for instance,  $1 - \lambda_i$  can be thought of as a proportional liquidation cost). Hence, the infinitely risk-averse lender will lend only up to  $\lambda_i \delta_i^{min}$  to be paid back by next period. Note that, to a large extent, as discussed below, alternative theories of repo contract determination in the existing literature amount to different drivers for the pledgeability parameter  $\lambda_i$ . Now, we are ready to express the risk-neutral borrower's willingness to pay for this repo loan given by:

$$\frac{\mathbb{E}[\delta_i]}{1 + R_{borrower}} + \lambda_i \delta_i^{min} \left( \frac{1}{1 + R_{repo}} - \frac{1}{1 + R_{borrower}} \right) - c \quad (2)$$

where the first term is simply the expected discounted value of the asset (as in the straightforward investment case) while the second and third terms encapsulate, respectively, both

---

<sup>7</sup>We are grateful to an anonymous referee for suggesting to us this stylized and illustrative representation of repo transactions.

the benefit of entering the repo at a lower interest rate than  $R_{borrower}$ , and the cost of the transaction,  $c$ . It is immediate that if the required returns of the two investors are elastic to the quantity of investments they hold, then in this stylized example the repo rates are determined by aggregate market clearing, unlike the haircuts on individual assets. The haircuts, on the other hand, are determined by the asset-specific largest risk-free payoff that can be pledged in the contract,  $\lambda_i \delta_i^{min}$ . This comprises two elements.

First, the intrinsic riskiness of the asset payoff – measured in this example by  $\delta_i^{min}$ , which is related to the asset’s fundamental risk. Second, the asset-specific pledgeability parameters  $\lambda_i$ , encapsulate a notion of liquidity (e.g., an asset characterized by a high price impact parameter would, ceteris paribus, command a lower  $\lambda_i$ ). The underlying rationale for illiquidity could be due to various reasons such as, e.g., asset-specific market development, difference of opinion, heterogeneous information about the asset fundamentals. To a large extent, as formalized below when presenting our testable hypotheses, different theories about the determination of haircuts are theories about the salient drivers of  $\lambda_i$  (and, to a lesser extent,  $\delta_i^{min}$ ). With the above stylized setting at hand, we now turn to the formalization of our testable hypotheses.

*Hypothesis 1 (collateral quality): The repo haircut is larger when the collateral is of lower quality and/or illiquid.*

That is, both a lower  $\delta_i^{min}$  and  $\lambda_i$  are expected to be associated, ceteris paribus, with a higher haircut. The literature generally agrees that collateral of lower quality commands a higher haircut. For example, in Holmstrom and Tirole (1997), the risky collateral leads to lower pledgeability and higher haircut. In Dang et al. (2011), they find that the haircut size depends on the quality of collateral since a repo haircut amounts to a “tranching” of the collateral security that discourages lenders from acquiring information, and tranche size depends on the risk characteristics of the collateral. In Martin et al. (2014), they argue that in bilateral repo markets, haircuts increase considerably with collateral risk and flexible haircuts make the bilateral market less fragile in terms of repo runs. In Brunnermeier and Pedersen (2009), haircut is pinned down by market Value at Risk (VaR) conditional on financiers’ information set. The authors show that when financiers are uninformed, they set destabilizing margins: when price deviates from fundamentals, they set high haircut and provide less funding liquidity, making price-fundamentals gap even larger and in turn reducing market liquidity.<sup>8</sup> In a contractual framework, Gottardi et al. (2019) also show that

---

<sup>8</sup>In their model, when financiers are informed, the opposite happens. The financiers provide more funding liquidity and lower the haircut when price is far away from the fundamentals and there is no feedback loop between funding and market liquidity in that case.

riskier assets command higher haircuts and lower liquidity premia, since higher risk entails a worse distribution of collateral value across states relative to collateral needs. In our stylized model in Appendix A.1, we find that repo haircuts are larger for riskier collateral, because borrowers are more likely to default, and for more illiquid collateral, because the recovery rate is lower (as stated in Proposition 1 therein).

We measure collateral quality using both proxies for the intrinsic risk of the assets, such as maturity, rating, and asset types, as well as the VaR of the asset, which is driven by the liquidity of the market in which the security is traded. Note that the VaR we compute is a market VaR (i.e. based on the uncertainty about the underlying asset price movements) rather than a credit VaR (normally based on transition probabilities across asset ratings and default states). Furthermore, the VaR measure is at the very short horizon (5 days). Given that the main driver of market VaR is the volatility of the price, it is greatly affected by the liquidity of the underlying (due to the effect of price impact). Instead, credit rating is not directly related to liquidity: only the likelihood of default should in principle affect this measure.<sup>9</sup> Nevertheless, there might be a feedback effect from default likelihood to liquidity of the asset: a low credit rating can cause an illiquidity of the asset, and hence also affect the VaR. The deal-level characteristics, such as notional value and maturity, are also likely to affect the overall risk and liquidity profile of the transaction. The larger the notional value, the larger the potential price impact in the event of liquidation. Similarly, as the length of the repo contract increases, the potential loss from worsening collateral quality becomes greater.

The existing empirical literature on bilateral repos (such as Gorton and Metrick (2012), Baklanova, Caglio, Cipriani, and Copeland (2019), Auh and Landoni (2022)) has examined how collateral risk characteristics, such as asset class, rating, and volatility affect haircuts. However, there is very little work to date on how counterparty (borrowers or lenders) characteristics affect haircuts. This is largely due to the fact that the existing datasets do not have detailed counterparty data or have data only from a single lender or only a single borrower.<sup>10</sup> Furthermore, prima facie, it is unclear whether counterparty characteristics should affect the haircut since the repo loan is overcollateralized. In fact, a European Repo council study (Comotto (2012)) has questioned whether counterparty characteristics should have an impact, if any, on haircuts. In contrast, existing theories based on various frictions do provide guidance on the possible impacts of counterparty characteristics. The rich cross-

---

<sup>9</sup>As per Moody's Rating Symbols and Definitions, 03/25/2025, page 47: "Moody's defines credit risk as the risk that an entity may not meet its contractual financial obligations as they come due and any estimated financial loss in the event of default or impairment. [...] Credit ratings do not address any other risk, including but not limited to: liquidity risk, market value risk, or price volatility."

<sup>10</sup>Baklanova, Caglio, Cipriani, and Copeland (2019) find suggestive evidence that counterparty risk is an important factor in explaining the dispersion of haircuts for repos involving Treasuries although the magnitude of its impact is small.

sectional variation of counterparty types in our dataset allows us to investigate the testable implications from different economic mechanisms proposed in the theoretical literature. We now motivate and formulate five hypotheses related to this channel via: counterparty type, default probabilities (of both borrowers and lenders), repeated interactions between counterparties, and lenders' liquidity needs.

*Hypothesis 2 (counterparty types): The repo haircut is larger when the counterparties in the contract are from different lines of business and hence have different opinions about the collateral value.*

That is, the difference in counterparty pair business models might affect the pledgeability of the asset ( $\lambda_i$  in our stylized description of a repo-financed asset purchase of equation (2)). Theoretically, Geanakoplos (2003) is the first to propose a general equilibrium framework with difference of opinion to study leverage constraints, and thus repo haircuts. The mechanism works as follows: optimists borrow from pessimists to speculate on the collateral value. Since pessimists do not value the collateral as much as optimists do, they are reluctant to lend, which constrains optimists' ability to borrow and results in a haircut. This means that the face value of the loan is lower than the market value of the asset. Simsek (2013) emphasizes that only the belief disagreement about the probability of the downside states has a significant effect on haircuts and asset prices. Since it is difficult to measure difference of opinion, we conjecture that when borrowers are from a different line of business from lenders, the potential belief disagreement is larger (especially for more obscure financial instruments like securitized products that are part of credit repo).

The literature on collateralized borrowing uses principal-agent models with borrowing constraints. As demonstrated in Simsek (2013), there is an equivalence of the principal-agent framework and the general equilibrium framework proposed by Geanakoplos (2010) as long as the optimistic borrowers have all the bargaining power. The principal-agent framework can be extended to include frictions other than belief disagreement, such as costly state verification, moral hazard (e.g. Holmstrom and Tirole (1997); Biais et al. (2016)), or adverse selection (e.g., Dang et al. (2011); Ozdenoren et al. (2023)).

Therefore, a potential proxy for information friction between the parties of a bilateral repo is the credit quality of the counterparty, rather than just the difference in types. Additionally, the existing empirical literature has been largely silent about how counterparty risk characteristics affect haircuts. This leads to our third testable hypothesis.

*Hypothesis 3 (counterparty quality): The repo haircut is larger when the default probability (credit quality) of borrower is higher (lower).*

That is, the borrowers' credit quality affects the collateral asset's pledgeability  $\lambda_i$ . Theoretically, borrowers' credit quality could affect haircut via several channels. In Gottardi, Maurin, and Monnet (2019), the authors find that haircuts increase when counterparty quality decreases because riskier borrowers can credibly promise to repay lower amounts. In Holmstrom and Tirole (1997), moral hazard is greater when borrowers have higher default risk and therefore borrowers need to put more skin in the game by taking a larger haircut. Biais, Heider, and Hoerova (2016) find that, in the presence of a moral hazard problem, there is less incentive for sellers to engage in risk prevention when their expected liability goes up. Larger haircut mitigates this moral hazard problem. Dang, Gorton, and Holmström (2011) show that the existence of haircuts is due to sequential trade in which parties may default and intermediate lenders face liquidity needs. In this setting, due to borrowers' default risk, haircuts need to be imposed to make repo debt information insensitive. Given the role of information frictions outlined above, a natural question is whether arrangements that have the potential to reduce information asymmetry are salient for equilibrium haircuts. For instance, the existence of repeated bilateral relationships between borrower and lender is likely to lower the degree of information friction, and hence could drive the determination of haircuts. This leads to our fourth testable hypothesis.

*Hypothesis 4 (bilateral relationship): Haircuts are lower for bilateral parties with stable banking relationships.*

That is, the information friction between the borrower and the lender affects the collateral asset's pledgeability  $\lambda$ . A stable banking relationship lowers the information friction. For instance, our stylized model (in Appendix A.1) captures the impact of information asymmetry on the collateral asset's pledgeability based on the canonical Akerlof (1970) framework. In this model, heightened information asymmetry between borrowers and lenders means that the repo market is more likely to be populated with low quality (lemon) collateral. Hence, the lender faces more severe adverse selection risk and demands a high haircut (see Proposition 2 in Appendix A.1). In Ozdenoren, Yuan, and Zhang (2023), Dang, Gorton, and Holmström (2013) and Dang, Gorton, and Holmström (2011) (just as in our stylized model in Appendix), a main driver of haircut is adverse selection. In Holmstrom and Tirole (1997) and Biais, Heider, and Hoerova (2016), the main driver is moral hazard. When information asymmetry is lowered, the impact of all above channels on haircut is reduced.

Nevertheless, as shown in Ozdenoren, Yuan, and Zhang (2023) and Proposition 3 of our stylized model in Appendix A.1, there are contractual ways to mitigate the impact of asymmetric information between the counterparties, and alleviate the risks faced by the lender. For example, a portfolio of collateral assets will have a larger borrowing capacity if it in-

cludes some safe assets. This leads to our next testable hypothesis.

*Hypothesis 5 (portfolio repos): Risky assets in a portfolio repo with safe assets have lower haircuts than purely risky asset repos.*

Finally, we examine whether the lender's characteristics affect haircut—that is, whether the lender's quality and liquidity affect the pledgeability of the collateral,  $\lambda_i$ .

*Hypothesis 6 (lender's quality and liquidity): The repo haircut is larger when the default probability and/or liquidity need of the lender is higher.*

This hypothesis draws on the literature that models coordination and runs in the repo market. Gorton and Ordonez (2014) find that endogenous information acquisition can cause a sudden increase in haircuts and a collateral crisis. In their setting, short-term collateralized debt is optimal if agents are willing to lend *without* producing costly information about the collateral backing the borrowing. This in turn endogenously generates financial fragility, as the quality of information about counterparty risk decays over time and a negative information shock might arise. When a shock realizes, the lenders optimally decide to acquire information about the quality of the collateral, causing in turn a credit crunch and a reduction in economic activity. Hence, in this setting, collateral quality and borrower characteristics determine the willingness of the lender to acquire information. In this model, lenders are homogeneous while borrowers are heterogeneous. Nevertheless, if lenders were to have heterogeneous costs of information acquisition, this would also drive their equilibrium action, making lender characteristics salient.

This intuition is formally developed in Dang et al. (2011). In their model, haircuts arise due to sequential trade in which parties might default and intermediate lenders face liquidity needs. Consequently, the drivers of haircuts become the following. First, borrower default probabilities (like in the testable hypothesis 3 above). Second, the nature of the collateral information sensitivity: like in our testable hypothesis 1 above, collateral with lower ratings has higher haircuts. Third, the liquidity needs of the lender and the default probability of the lender, since the lender might need to raise funds by further pledging and/or liquidating the received collateral. This channel causes lenders with higher liquidity needs to charge higher haircuts. Similarly, in a dynamic Diamond and Dybvig (1983) model with a collateral market, Martin, Skeie, and Von Thadden (2014) study the role of liquidity and collateral constraints in determining repo runs. They find that the value of collateral and the endogenous liquidity of intermediaries then become crucial for their stability, as repo runs can be avoided by mobilizing sufficient liquidity and having sufficiently valuable collateral.

That is, the “balance sheet liquidity” of the lender becomes a key driver of repo contract terms and market conditions.

In addition to the above hypotheses for equilibrium haircut drivers, the stylized formulation in equations (1)–(2) suggests a “pecking order” for collateral posting by repo borrowers. The idea is simple: if the borrower chooses whether or not to repo an asset based on which of the two expressions is higher, assets which can back the most safe debt (i.e., assets with larger  $\lambda_i \delta_i^{min}$ ) will be repoed first. We investigate this conjecture in our empirical analysis.

### 3 Overview of the Data

The transaction-level dataset is a snapshot of the repo books of six banks that are major players in the UK repo market. The total size of their repo books—the sum of repos and reverse repos—is around £511 billion (including CCP transactions) at the end of 2012.<sup>11</sup> According to Financial Stability Board (2013), the UK-resident deposit-taking banks hold around £2.1 trillion in gross repo activity on their balance sheets, hence our dataset accounts for around 24% of the total repo activity in this market. That is, these six banks are, in terms of activity, central to the UK repo market, and are in our sample because the regulator deemed them systemically important for the repo market. The majority of this business is with non-UK resident banks, including the activity between UK and foreign branches of the same consolidated group, and is highly concentrated (Financial Stability Board, 2013). Each of the six banks reports its outstanding repo transactions as of the end of 2012, including the gross notional, maturity, currency, counterparty, haircuts and collateral information. We supplement this dataset with additional data on securities, counterparties, and the reporting banks from Datastream and Bloomberg. In what follows, we report information and results for reverse repos (REVR) and repos (REPO) separately. This classification is from the point of view of the reporting banks. Hence, *in a reverse repo the reporting bank is lending* to a counterparty, and *in a repo the reporting bank is borrowing* money from a counterparty.

#### 3.1 General Sample

Table 1 presents an overview of our dataset in terms of key repo and reverse repo contract characteristics. It shows the breakdown of the data along four categories: maturity, currency, counterparty type, and collateral type (Panels A, B, C, and D, respectively). Since repo indicates bank borrowing, we denote the repo values with negative numbers. By comparing the values of reverse repos and repos, we find that the reporting banks are net borrowers in the

---

<sup>11</sup>The actual reporting periods differ slightly across the banks, but all are toward the end of 2012.

repo market (see the row labeled "Total" in Table 1). Panel A of the table shows that most of the borrowing and lending transactions for these reporting banks have maturities less than three months. While borrowing exceeds lending for overnight contracts, lending is larger for transactions with maturities of less than three months. This observation suggests that the reporting banks conduct maturity transformation, to some extent. However, for maturities longer than one year they are still net borrowers. Panel B of the table shows that the reporting banks borrow and lend the most in GBP and EUR followed by USD. In net terms, they borrow in GBP and lend in other currencies. Panel C of Table 1 shows that the reporting banks, in aggregate, borrow more via CCPs and from counterparties such as other banks, central banks and governments, broker-dealers and hedge funds. The reporting banks lend more via CCPs and to counterparties such as other banks, hedge funds, broker-dealers, and other asset managers. This is in line with our general understanding of the money flow pattern in the wholesale funding market where banks and CCPs intermediate repo trades.<sup>12</sup> Finally, Panel D of Table 1 shows the breakdown based on collateral types. It shows that when the six banks borrow, only a small percent of their repo collateral is U.S. government bonds. It also appears that the reporting banks intermediate in (and borrow against) relatively worse collateral such as securitization products and corporate debt. UK government bonds are the most common collateral used both in repo and in reverse repo contracts followed by other high quality sovereigns such as German government bonds. Inspecting the maturity-currency relationship in Figure 1, we see that the majority of contracts (frequency, not notional values) are in EUR and USD followed by GBP and JPY. Most of the contracts have maturity less than 3 months across all currency groups. Only a very small fraction of the contracts have maturity more than half a year within each currency category. GBP has a relatively higher fraction of reverse repo contracts within 3 to 6 months, compared to other currencies. Repo (reverse repo) transactions in JPY and other currencies happen almost exclusively with maturity up to 1 (3) month(s). In Table 2, we examine the breakdown of contract characteristics for the CCP sub-sample. There are six CCPs in our sample. Compared with the full sample, the CCP subset is less heterogeneous in terms of maturity, currency denomination and types of collateral. CCP trades are mostly short-term with 1 day to three-month maturity and without any maturities above five years. GBP-denominated transactions are above 82% for repo and above 55% for reverse repo CCP trades. UK government bonds are featured as collateral in 86.7% of the repo and 59% of the reverse repo CCP trades.

---

<sup>12</sup>The first row in Panel C describes the values when counterparty is a reporting bank. The reporting banks report on a UK-consolidated basis, but counterparties are reported on a global basis. Therefore, there may be discrepancies between the reverse repos and repos with the reporting banks.

Finally, to contrast the effect of the collateral quality, we provide summary statistics for three salient subsamples: Government securities rated AA and above, as well as rated below AA, and finally other securities. This exercise also serves to compare with studies using the U.S. tri-party repo data where collateral consists of high-quality U.S. treasuries. The breakdown of these three types of contracts across maturity, currency, and counterparty types is shown in Table 3.

There are several notable differences between repos backed by highly-rated government securities and non-government ones. First, contracts with non-government assets as collateral are mostly overnight in reverse repo, and longer-term (1-5 years) in repo. This fact shows that when banks lend against riskier collateral (reverse repo), they do so only for very short maturities (overnight), whereas when they borrow against this risky collateral, they are able to do so for much longer contract maturities. In contrast, the safest collateral (AA or higher government securities) is used both for repos and reverse repos with maturity up to 1 year, and the distribution across maturities is fairly similar. The intermediate quality collateral (government assets rated below AA) is used extensively for short-term repos and reverse repos with maturity of less than three months.

Second, the lower rated government securities and the non-government collateral have a larger share of USD-denominated trades, while the safest government assets are used to borrow mostly in GBP. The share of hedge funds as counterparty for non-government securities is larger when the reporting banks are lending compared to when they are borrowing. The larger share of hedge fund borrowers might explain the short overnight maturities of these contracts given the higher riskiness of hedge funds. In contrast to the case of non-government collateral, the repos backed by the safest assets have the majority of deals (both repo and reverse repo) with CCPs.

Comparing the total for the safest government collateral in repos and reverse repos in Table 3 (£314.4 billion) to the total in Table 1 (£511.2 billion) shows that a significant portion of the repo market – about 39% – is backed by riskier collateral. This is a phenomenon that is unique to the European market and is a significant departure from the patterns observed in the U.S. repo market. Among the 39%, about 7% is backed by non-government collateral, which is of lower average quality. The discrepancy between our sample and the general U.S. market stems from the fact that risky sovereign bonds such as those issued by GIIPS (Greece, Italy, Ireland, Portugal, and Spain) and developing countries are accepted as collateral by central banks in the European markets, but not in the U.S. market. Since the repo literature is dominated by studies that use U.S. data, in the haircut analyses below we differentiate results for different collateral types. This investigation is in addition to the main analysis using the whole sample, in order to assess whether the overall results are mainly driven by

a subsegment of the market.

We also analyze to what extent collateral is reused in our dataset by computing what percentage of the collateral received by banks in reverse repos is then reused to borrow as part of repo transactions. In particular, we report in Table 4 the average rehypothecation rates by maturity and collateral type. The overall pattern of rehypothecation across maturities is similar to recent findings for the U.S., as in Figure 4 of Infante et al. (2020). Table 4 shows that rehypothecation is more common for higher quality government securities particularly at 10-20 year maturity. Conversely, non-government collateral is rehypothecated at much lower frequency, especially for longer maturity.

Since we explore the heterogeneity of non-CCP deals in a large part of our regression analysis, Table 5 presents summary statistics on haircuts for the non-CCP subsample along four categories: maturity, currency, counterparty type, and collateral type (Panels A, B, C, and D, respectively). This sample is also smaller than that in Table 1 due to missing haircut information for some observations. The average haircuts for each category in Table 5 are weighted by the gross notional of transactions.

Panel A of Table 5 shows that, except for long maturities, the reporting banks are able to borrow at slightly lower haircuts than they lend. This observation means that they can use the collateral received in a reverse repo to obtain cheaper funding. A similar pattern exists for different currencies as shown in Panel B. Panel C makes it clear that the above-mentioned haircut advantage for reporting banks arises from trades with hedge funds, other asset managers and, to a lesser extent, with other banks and broker-dealers. In the transactions with these counterparties, the banks can receive funding at significantly lower margins. The intermediation spread can be as high as 1.3% for hedge funds and as low as 30 bps for broker-dealers. This advantage disappears when our banks trade with central banks and government agencies, insurance companies and pension funds, and other reporting banks.

Finally, Panel D in Table 5 shows the breakdown based on collateral types. It displays how margins depend on the quality of collateral. For example, both repos and reverse repos for German government bonds have a low average haircut, while haircuts for corporate debt and securitization are higher. The numbers also show that the six reporting banks are able to borrow at a lower haircut compared to the one they charge for the same type of collateral. This is true for all collateral types, except securitized debt. Note that the UK government collateral commands a relatively high haircut, but this is largely due to the longer maturity of the collateral.

## 3.2 Zero-haircut Subsample

There are many zero-haircut observations in the data as illustrated by the histogram of haircuts in Figure 2: over 35% of the whole sample. Some of these zero haircuts are due to the way haircuts are reported in CCP trades as explained in the next section, but even excluding CCP trades, zero-haircut transactions are still quite common.<sup>13</sup> This finding is not surprising and has been confirmed by other data collections undertaken at the global level. A summary of the zero-haircut trades among the non-CCP sample is presented in the last two columns of Table 5. The table shows that the vast majority of contracts are with other banks and are denominated in EUR. In terms of notional values, most repo contracts are overnight, whereas reverse repos have maturities below 3 months. As for number of contracts, most of the zero-haircut contracts are overnight (84% of all repo contracts, 72% of all reverse repos), as shown in Figure 3.

The network graphs in Figure 4 illustrate the topology of the zero-haircut trades. The size of each node reflects the number of counterparties with which a reporting bank has at least one zero-haircut deal. Edge widths show the total number of zero-haircut trades between two given nodes. The figures show that the zero-haircut observations from the repo and the reverse repo samples are dominated by one or two banks. In the repo market, one of the banks (bank A in Figure 4) receives the majority of zero-haircut trades. This borrower has 89 zero-haircut lending counterparties but one particular counterparty accounts for 24% of these trades – C697 in Figure 4. In the reverse repo market, another bank (bank B in Figure 4) is involved in 95% of all the zero-haircut trades. The top-10 counterparties account for 68% of all zero-haircut repo trades and 71% of all zero-haircut reverse repo trades, which shows that a small number of counterparties contribute to the majority of zero-haircut observations. These facts suggest (and the fixed-effect analysis in Section 4.2 confirms) that there are important borrower-lender relationships among the determinants of the zero-haircut trades, supporting our fourth testable hypothesis highlighted above. We investigate the role of bilateral relations further in later sections.

## 3.3 Complementary data on repo rates

Unfortunately, despite its richness, our baseline dataset does not include interest rates on the repo contracts. To fill this gap we employ the Bank of England Sterling Money Market daily (SMMD) dataset that contains detailed transaction-level information on repo and reverse repo agreements for which GBP cash borrowing and lending is secured against Treasury bills and government bonds (nominal and index-linked Gilts) issued by the UK gov-

---

<sup>13</sup>We find that zero-haircut trades are about 36% of the CCP sample and 30% of the non-CCP sample.

ernment. Our data include trades reported by banks and major broker-dealers between 2016 and 2019.<sup>14</sup> The data include, among other information, the counterparty Legal Entity Identifiers (LEI), the amount, the maturity of the transaction, and corresponding interest rate, the ISIN identifier for the collateral backing the transaction, and the market value of the collateral. Summary statistics for this data are reported in Tables OA.I–OA.III of the Online Appendix.

## 4 The Drivers of Haircuts

### 4.1 Empirical approach

For most of the regression analysis, we focus on the sample excluding the trades with CCPs. In practice, CCPs often calculate haircuts (or initial margin requirements) on a portfolio basis. That is, the over-collateralization of repo positions is calculated at the portfolio or netting set level, without applying haircuts on individual transactions. In our dataset, firms still report a transaction-level haircut, but this is often zero given that the ‘true’ haircut is applied at the portfolio level. In such cases, it is not meaningful to look at haircuts on individual transactions that are centrally cleared. Therefore, we focus on the sample that excludes CCP transactions to conduct the main analysis. Nevertheless, we also study the reasons for choosing CCPs to conduct trades in Section 4.4.

In Table A.I of the Appendix, we describe all the explanatory variables used in the regressions. We have dummy variables for currencies, collateral types, counterparty types, bank-counterparty pairs and a dummy for collateral bundled in a portfolio with a very safe asset (rated AAA). Other than dummy variables, we use trade-specific variables, collateral-specific and counterparty-specific characteristics. We also have two measures for counterparty and collateral concentration. Counterparty concentration measures the share of transactions with a specific counterparty in total, evaluated using the notional amount of transactions. It represents how important that counterparty is to the bank. Similarly, collateral concentration is measured by the share of transactions against a specific collateral in total, evaluated using the notional amount of transactions. We also include an interaction between counterparty and collateral rating to check for substitution effects between the two types of ratings.

To confirm that the large number of zero haircuts does not distort our results, in addition

---

<sup>14</sup>The Bank of England requires institutions with a significant activity in the money market to report their transactions. The population for the daily transaction reporting is chosen to capture all institutions whose activity falls within the top 95% of activity at either overnight or up to one-year maturity (measured using their reported annual turnover).

to the ordinary least square regressions, we also report Tobit estimation with truncation at zero (in the Appendix, Table A.II). We split the data and consider separately repo and reverse repo transactions since they are different samples: one has reporting banks as borrowers and the other has the reporting banks as lenders. Moreover, we observe heterogeneity in the counterparties in the two types of transactions which allows us to conduct a more detailed analysis of haircut determinants.

Table 6 reports summary statistics for haircuts and non-dummy explanatory variables for the sample used in the baseline regressions. Except collateral and counterparty ratings, which are categorical, other variables in this table are continuous. The summary statistics are presented separately for reverse repos and repos in Panels A and B, respectively, given that haircut practices can potentially differ significantly between the two instruments. Variables are winsorized at the 0.5% level.

Even though haircuts can have a value as high as 46%, the weighted average of haircuts is about 6% for reverse repos and about 2% for repos. The weighted average of maturity for the transactions is about 22-29 days. The average collateral maturity is between 7.5 and 12 years. Collateral and counterparty ratings are converted to a numeric scale from 1 to 20, with 20 being the highest rating. The average collateral quality in this scale is about 14, while the average counterparty rating is between 14 and 15 (which corresponds to between A- and A).

The summary statistics for counterparty return on assets (RoA), leverage, CDS spread, and cash ratio are also presented in Table 6, and the respective definitions are in Table A.I. We include RoA to see how the profitability of the counterparty can affect haircuts. The cash ratio is intended to proxy for liquidity needs. Overall, the summary statistics for reverse repos and repos are not significantly different. We also present the same data for different subsets of collateral types in Table 7 and, overall, the counterparty characteristics seem similar across the three collateral categories.

Table 8 reports the baseline estimation results for the whole sample using the OLS specification. We conduct the analysis separately for reverse repo and repo contracts because for the same bilateral pair, the bargaining power often lies with one party regardless of whether this party is borrowing or lending. Therefore, haircuts would be different when the party with the greater bargaining power is borrowing (repo) compared to when it is lending (reverse repo), indicating that the counterparty fixed effect estimation should be different for the reverse repo and repo contracts. We also report the subsample analysis for different categories of collateral in Tables 9 (reverse repo) and 10 (repo), to isolate the information effect of the collateral on the haircut determination.

In these three tables, the dependent variable is haircut. The explanatory variables are

classified into five categories: deal characteristics, collateral characteristics, counterparty types, counterparty characteristics, and miscellaneous variables. These categories are shown in the first column. Numbered columns display regression coefficients for different sets of explanatory variables. All continuous explanatory variables are standardized in order to simplify the comparison of coefficients for different variables. Standard errors, which are not reported for simplicity, are clustered at the counterparty level.<sup>15</sup> All regressions include bank fixed effects (FEs), relationship fixed effects and currency fixed effects. A relationship FE is a dummy taking the value of 1 if the given dealer-counterparty pair has more than 10 trades in the regression sample.<sup>16</sup> The main regression for Table 8 is:

$$Haircut_j = \beta \times determinants_j + BankFE + RelationshipFE + CurrencyFE + \epsilon_j, \quad (3)$$

where  $\beta$  is a vector of estimates on the haircut determinants.

In columns (1)-(5) of Table 8 we report the findings for reverse repo transactions. In these transactions, the reporting bank lends cash and receives collateral, whereas the counterparty borrows money and delivers collateral to the bank. Hence, counterparty characteristics correspond to borrower characteristics. In columns (6)-(10), we present analogous results for repos. In these transactions, the reporting bank borrows cash and delivers collateral, whereas the counterparty lends money and receives collateral. Hence, counterparty characteristics correspond to lender characteristics in these transactions. In both cases, we first report the result with the smallest set of explanatory variables (deal characteristics), then we include collateral variables, counterparty types and characteristics variables, and finally a set of miscellaneous variables.<sup>17</sup>

In Tables 9 (reverse repo) and 10 (repo), we present results for the three subsets of collateral: Government securities rated AA and above, those rated below AA, and non-government (other) securities. The regressions therein are of the form

$$\begin{aligned} Haircut_j = & \gamma \times determinants_j + \beta_1 \times determinants_j \times D_{j,<AA} \\ & + \beta_2 \times determinants_j \times D_{j,Other} + \delta_1 D_{j,<AA} + \delta_2 D_{j,Other} \\ & + BankFE + RelationshipFE + CurrencyFE + \epsilon_j, \end{aligned} \quad (4)$$

where the  $\gamma$  coefficients measure the base effect (corresponding to highly-rated government

---

<sup>15</sup>We have explored using two way clustering at the bank and counterparty levels, yielding similar results. However, given that we have only six banks in our sample, we have too few clusters at the bank level. Hence, we report standard errors using single clustering in all our tables.

<sup>16</sup>The results with larger cutoffs are similar.

<sup>17</sup>In Table A.III in the Appendix, we also run a robustness test for the main regression specification including month fixed effects, which shows that the main results are unchanged.

assets), shown in columns (1)–(5), and the  $\beta_1$  and  $\beta_2$  coefficients capture the marginal effects, i.e., the relative effect of using, respectively, government assets with ratings below AA (in columns (6)–(10)), and other collateral (in columns (11)–(15)).

In all tables, reverse repo regressions have a better fit (measured by  $R^2$ ) than repo regressions. Importantly, the marginal  $R^2$  pertaining to the various groups of explanatory variables is lower for repo than for reverse repos. For example, in Table 8, adding all our regressors in the repo case gives an  $R^2 = 0.532$  (column 10) compared to having only the two contract-specific variables (column 6) with  $R^2 = 0.511$ . For reverse repos, adding all the regressors increases the  $R^2$  from 0.539 to 0.669. Overall, this shows that our empirical model is better at explaining reverse repos than repos. This observation is also corroborated by there being fewer significant coefficients in the case of repos compared to reverse repos.

The above observation can be partially explained by the nature of our sample. The reverse repo sample consists of the lending transactions by the six major banks to a variety of counterparties who use various types of collateral. Hence, there is more heterogeneity in both collateral and counterparty characteristics for the regression analysis, which could explain the better fit. In contrast, the repo sample contains borrowing transactions by the same six major banks who use a more limited range of collateral and borrow from a relatively smaller set of counterparties (since typically only cash-rich counterparties lend to the banks). These unique features of our sample could help explain the difference in regression fit across the repo and reverse repo subsamples. Next, we elaborate on the main results presented in Tables 8–10 in light of the six hypotheses formulated in Section 2.

## 4.2 Tests of hypotheses

*Test 1 (collateral quality): The haircut is larger when the collateral is of lower quality and/or illiquid.*

As mentioned earlier, collateral quality can be measured using VaR, maturity, rating, and/or asset types. Transaction maturity is also a proxy because the longer the maturity, the riskier the underlying collateral becomes. Another measure of collateral riskiness is its concentration: when the concentration ratio increases, the collateral portfolio pool becomes riskier. To test hypothesis 1, we include VaR of each asset, collateral rating, maturity, transaction maturity, collateral concentration, and notional value in all baseline regressions. We compute VaR using two approaches. First, the measure is obtained using the historical approach, i.e., using the quintiles of the historical return distribution. We calculate simple returns and take the 5-days, 5% VaR as our main measure.<sup>18</sup> Second, we also compute VaR

---

<sup>18</sup>Using 1% or 10 days produces similar results.

using the parametric approach (i.e., using the deciles of the normal distribution). The results are largely similar to the results obtained using the historical approach. In the main text, we provide the results obtained with the historical VaR.

Table 8 shows that the longer the contract maturity, the larger the haircut, and this relationship is statistically significant across most specifications. The estimate of 0.054 in column (5) of Table 8 shows that one standard deviation increase in maturity of reverse repo contracts (2 months) raises haircuts by 5.4%. Similarly, the coefficient of 0.035 in column (10) shows that one standard deviation increase in maturity of repo contracts (4 months) raises haircuts by 3.5%.

Among the collateral qualities, the results in Table 8 show that VaR has the most consistent, statistically significant impact on haircuts – both in reverse repo and repo markets. One standard deviation increase in the 5-day, 5% VaR is correlated with 100 bps increase in the repo haircut and with a 60 bps increase in the reverse repo haircut. The effect is robust to adding different controls – the estimates in columns 1-10 barely change. When inspecting the impact of VaR in the collateral subsets, we find that this effect is robust for reverse repo cash transactions, but the marginal effect is negative for lower rated government bonds and not significant for non-government collateral (see Table 9). This reinforces the conjecture that, given its short horizon, VaR captures mostly liquidity rather than credit quality.<sup>19</sup> VaR is insignificant for repos for all collateral categories (see Table 10).

We find that collateral rating has a statistically significant impact on reverse repo haircuts. One unit increase in collateral rating lowers the haircut by about 1.2% (Column (5) in Table 8). That is, the reporting banks rely on collateral rating to assess the haircut when lending. However, the statistical significance of this result disappears for the repo sample. This indicates that when reporting banks borrow, their counterparties rely less on collateral rating (a credit risk indicator) but more on VaR (a liquidity indicator) to set the haircut.

For the whole sample, higher collateral concentration – another measure of the riskiness of the collateral portfolio – increases the haircut, both for reverse repo and repo transactions (columns (5) and (10) in Table 8). Therefore, our reporting banks are charged (charge) significantly higher haircuts when borrowing (lending) relatively large sums against the same collateral. The results are more subtle when conditioning on the three collateral subsets.

Collateral concentration has a positive and statistically significant effect on haircuts only when the reporting banks are lending against riskier collateral (column (15) in Table 9).

In general, there is strong evidence that collateral quality and liquidity variables are important determinants of repo haircuts.

---

<sup>19</sup>VaR is a measure of market liquidity risk in standard risk management textbooks.

*Test 2 (counterparty types): The haircut is larger when the counterparties in the contract are from different lines of business and hence have different opinions about the collateral value.*

Table 8 shows that the reporting banks charge higher haircuts when lending to hedge funds and are charged higher haircuts when borrowing from central banks. However, there is more complexity to this finding. In Table 9 we further examine this effect in separate subsets of collateral. We find that hedge funds are charged much higher haircuts when using non-government assets as collateral: the haircut increases by a staggering 25-28% when banks lend to hedge funds in a repo backed by non-government securities. This finding is consistent with the idea that belief disagreement is more pronounced for repos backed by risky collateral. Somewhat surprisingly, banks charge lower haircuts when hedge funds use highly-rated government assets as collateral. The latter observation might be related to the fact that the type of hedge funds that borrow using high quality collateral is different from the one using riskier collateral (Krutli et al. (2021)). We also observe a similar dichotomy for insurance companies and pension funds, although the aggregate impact on the haircuts paid overall (shown in Table 8) is not statistically significant.

Since there is more disagreement about the value of riskier and more heterogeneous collateral relative to the safest government bond collateral, these observations support the view that when the two parties in a repo contract disagree on the collateral value, charging a higher haircut is a tool to mitigate the disagreement. We do not find strong evidence that banks charge significantly higher haircuts when lending to broker-dealers, other banks, or asset managers. This pattern might reflect the fact that there is lower information friction between counterparties of similar types. This evidence is consistent with both the difference of opinion (see, e.g., Geanakoplos (1997)) and the adverse selection (see, e.g., Ozdenoren et al. (2023)) paradigms.

However, although our reporting banks are charged higher haircuts when borrowing from several types of counterparties in our sample, only haircuts from central banks are significantly larger from a statistical standpoint – about 4.9% higher (column (10) in Table 8). This effect is present only if banks use the safest government collateral (Table 10). Overall, the lack of significant counterparty type fixed effects in the repo sample (except the central banks one) may reflect the fact that there is little disagreement about the value of collateral used by the reporting banks (since collateral is mostly of the highest quality – see Table 3), and higher costs in accessing central bank liquidity.

*Test 3 (counterparty quality): The haircut is larger when the default probability (credit quality) of the borrower is higher (lower).*

To test hypothesis 3, we use the rating and the leverage ratio of the borrower in the

reverse repo sample. The results from Table 8 show that both have a significant impact. Our reporting banks charge higher-rated (lower default probability) borrowers and lower-levered banks lower haircuts: one unit increase in rating decreases the haircut by 1.7% and one standard deviation drop in leverage lowers the haircut by 7.7% (column (5)). These findings are consistent with the third hypothesis. The results in column (5) of Tables 8–9 also show that larger counterparties are charged lower haircuts by our reporting banks: one standard deviation increase in size massively reduces the haircut by 15.8% (and this seems to be driven mostly by the highly-rated government collateral, see Table 9). This finding shows that there is significant tiering in the repo market, similar to that in other short-term funding markets (Rime et al. (2022)). The results for the repo sample are not statistically significant although the positive sign indicates that larger lenders charge a higher haircut. Counterparties with missing data on counterparty characteristics charge a higher haircut as lenders, but receive a reduced haircut as borrowers. The majority of these counterparties are small banks, asset managers, and some hedge funds.

*Test 4 (bilateral relationship): The repo haircut is lower for bilateral parties with a stable banking relationship.*

Although our baseline dataset comprises a static snapshot of repo and reverse repo portfolios, we do actually observe repeated interactions across time. The snapshot covers trades initiated in the past at different moments in time, which allows us to observe several outstanding contracts between two counterparties. These repeated interactions enable us to tease out bank-counterparty variation that is unexplained by the controls, which is the base for our measure of relationships. In particular, we measure bilateral relationships with bank-counterparty fixed effects and focus only on pairs with at least 10 contracts outstanding. This allows us to distinguish between pairs that traded often in the past and those that did not. Table 11 reports the percentages of significantly negative and positive relationship fixed effects in specifications with and without bank fixed effects. It shows that an overwhelming majority of relationship fixed effects yield statistically significant negative haircuts. The reduction in haircut is around 7-10 basis points for reverse repo transactions, and 4-6 basis points for repo transactions. The results indicate that bilateral banking relationships indeed reduce the haircut.

Figure 5 presents a network graph of all the bank-counterparty relationship fixed effects, significant at the 5% (one-sided) level. Red color means the regression coefficient on the fixed effect is negative (lower haircut if the given two nodes enter a repo contract). Blue color means the coefficient is positive, i.e. higher haircut if the two nodes enter a contract. The thickness of the edge between two nodes shows the magnitude of the coefficient on the

relationship fixed effect. The size of each node reflects the number of significant fixed effects involving the node.

The figure is consistent with the hypothesis that bilateral relationships matter in haircut determination since some entities are consistently able to borrow at a lower haircut from a set of counterparties. For example, bank B both borrows from and lends to counterparties C115, C167 and C189 at a significantly lower haircut. Interestingly, the same bank also lends at zero haircut to the largest number of counterparties, and also borrows at zero haircuts from many entities as seen from Figure 4. Bank A, which is also a major zero-haircut borrower and lender, is also involved in several significant relationships as seen from Figure 5 but the bank also charges or is charged higher haircuts when interacting with a set of counterparties as indicated by the blue lines. Overall, we find evidence in support of the fourth hypothesis and show the importance of bilateral relationships in determining haircuts.<sup>20</sup>

*Test 5 (portfolio repos): Risky assets in a portfolio repo with safe assets have lower haircuts than purely risky-asset repos.*

To implement this test, we define a dummy equal to one if an asset is part of portfolio which contains at least one highest-rated asset (AAA). The coefficient on the dummy for collateral bundled in a safe-asset portfolio from Table 8 shows that lower-rated assets in a portfolio with a safe asset have lower haircuts (about 60 bps) in the reverse repo sample compared to the same assets in a standalone arrangement. A more detailed analysis of the safe-asset portfolios shows that lower-rated counterparties are more likely to bundle assets in such portfolios. Hedge funds are the counterparties with the largest fraction of portfolios bundled with a safe asset. The effect of a safe asset in a portfolio is, however, not statistically significant for the repo sample. Overall, there is mixed evidence for this hypothesis.

*Test 6 (lender's quality and liquidity): The repo haircut is larger when the default probability and/or liquidity need of the lender is higher.*

In the reverse repo regressions, the lenders are the reporting banks and borrowers are various counterparties. In the repo regressions, the lenders are various counterparties. Table 8 shows that none of the counterparties in the repo regressions affect the haircut except for central banks and government. In addition, none of the counterparty characteristics coefficients other than that of counterparties with missing data is consistently statistically

---

<sup>20</sup>The bilateral relationships might stem from interactions between the two entities in markets other than the repo market. For example, a customer might also have an established trading relationship with the bank in other, non-repo assets. Examining the drivers of bilateral relationships is an interesting question that is beyond the scope of this paper since we do not observe interactions beyond those in the repo market.

significant. The estimates on lender’s cash ratio, which could be a proxy for lender’s liquidity needs, is insignificant. Similarly, the estimates on lender’s CDS and leverage, which could proxy for default probability, are also not significant, whereas the coefficient on rating is positive but only marginally significant. These findings are not strongly supportive of hypothesis 6 and indicate that lender’s default probability or liquidity needs do not affect how lenders set haircuts in repo contracts.

### 4.3 Likelihood of zero-haircut repos

Given the large number of zero haircuts in the data, we now study which transactions are more likely to get a zero haircut. To do that, we replace the independent variable with a dummy taking value 1 if the haircut is zero and value 0 otherwise:  $D_{j,zero\ haircut}$ . We then estimate a simple OLS (a linear probability model) where the regression coefficients on the independent variables can be interpreted as marginal effects on the probability of observing zero haircut on a given contract:

$$D_{j,zero\ haircut} = \beta \times determinants_j + BankFE + RelationshipFE + CurrencyFE + \varepsilon_j. \quad (5)$$

Table 12 shows that the  $R^2$  is very high in all regressions, suggesting that the explanatory variables capture most of the variation in zero versus non-zero haircuts. A closer look shows that the relationship FEs explain the largest part of that variation. In addition, collateral quality and liquidity variables affect the probability of receiving a zero haircut in a way similar to the size of haircut, which we studied earlier. Lower contract maturity and higher collateral rating increase the probability of receiving a zero haircut in the reverse repo sample. Riskier counterparties (as measured by their CDS spreads) are less likely to receive a zero haircut. We also find that the probability of a zero haircut is higher when the counterparties are broker-dealers, central banks, asset managers, or even hedge funds (a marginally significant effect in reverse repo).<sup>21</sup>

### 4.4 Determinants of CCP trades

We now examine the characteristics of trades with CCP as the counterparty. Four out of the six reporting banks in our analysis are involved in transactions with CCPs. In our baseline data, there are nine counterparty legal names for the CCPs, but several of them are variations of the same names. Consequently, there is some degree of variation in the

---

<sup>21</sup>The evidence pertaining to the role of relationships in affecting zero haircuts adds to the recent U.S. evidence of Baklanova et al. (2019).

type of collateral accepted by the different CCPs, as some of them explicitly exclude more risky securities (such as corporate debts, MBS and equities) from the pool of accepted collateral.<sup>22</sup> Transactions with CCPs require the maintenance of a margin account on both repo and reverse-repo transactions, charging an effective haircut on both repo and reverse-repo transactions to reduce counterparty risk, as well as a contribution to a default fund. Overall, in CCP-cleared repos, margin requirements tend to be standardized and generally more conservative (see Table 13).

In our sample CCP trades are associated with the use of highly-rated government bonds as collateral (see Table 2). In addition, they consist of a large share of UK government bond collateral (59% and 86.7% respectively for reverse repo and repo).

In general, CCP repos can use as collateral a specific asset, a portfolio of assets, or a general collateral from a specific pool of accepted assets. In the latter case there is a potential element of adverse selection, as banks might decide to use only the ‘unwanted’ assets eligible for the collateral pool.

While our baseline dataset does not allow us to distinguish between general and specific collateral transactions, this information is available in the SMMD dataset which focuses on GBP cash borrowing and lending secured against Treasury bills and government bonds issued by the UK government. For these transactions with CCPs, Figure 6 reports the shares of repo and reverse repo contracts for which the collateral is identified by a single ISIN (“Single ISIN”), contracts in which multiple securities are identified by single ISINs (“Multiple ISIN”), i.e. “portfolio repos,” and finally contracts for which the eligible collateral is represented by a pool or basket of securities (“Pooled ISIN”).

We observe that *specific* collateral deals account for the majority of outstanding reverse repo and repo transactions across the sample. This pattern is more pronounced when reporting banks are lending (reverse repo) than when they are borrowing (repo), as the share of specific collateral transactions ranges respectively between 95.6% and 98.3% for reverse repo and 91% and 97% for repo. The figure also highlights that transactions against a pool of collateral account for a larger share of the total when value-weighting the transactions by their nominal amount.<sup>23</sup> This is particularly true when the reporting banks borrow (repo transactions). Note that these results are likely to provide a lower bound on the importance of specific collateral transactions in our earlier sample as the introduction of the cleared term delivery-by-value (DBV) service for sterling general collateral repo trades in late 2013/early

---

<sup>22</sup>See Table 3 of Reserve Bank of Australia and Australian Securities and Investments Commission (2015) for a summary of the collateral types accepted by the main CCPs.

<sup>23</sup>Transactions against a pool of collateral account for 1.69% to 4.12% of reverse repo and 2.87% to 9.02% of repo transactions. When the nominal amount of the transaction is used as weight, these shares are respectively 5.21% to 13.4% and 13.0% to 34.9%.

2014 is likely to have resulted in an increased use of this type of deals.

In unreported regressions we use the entire sample including the CCP deals and re-run the main regressions. None of the results mentioned above changes significantly, with one exception. We observe that including CCP transactions attenuates the impact of counterparty concentration on increasing haircuts, suggesting that our reporting banks do not view concentration of transactions with CCPs as increasing risk. As discussed in Schaffner et al. (2022) and Ballensiefen et al. (2023), by interposing themselves between borrowers and lenders CCPs greatly reduce counterparty risk, and apply the same collateral and risk policies to all CCP members, generating a more homogeneous set of collateral than for our non-CCP sample (see Panel D of Table 1 and Panel C of Table 2).

In Table 13, we compare CCP versus non-CCP transactions. One immediate observation is that when our reporting banks transact through CCPs, they earn lower intermediating spreads, since they are borrowing at a higher average repo haircut via CCPs (at 0.044) than from non-CCP counterparties (at 0.039), and lending out at a lower average reverse repo haircut via CCPs (at 0.071) compared to non-CCP counterparties (0.096). Table 13 also shows that transactions with CCPs are more likely to have zero haircut. Nevertheless, trades with CCPs offer a significant advantage over non-CCP transactions because CCP trades are netted and expand banks' balance sheet less.

To elicit whether the reporting banks are indeed utilizing this netting benefit, we compute the ratio of total repo and reverse repo positions against a given counterparty from the point of view of reporting banks in our sample. Table 13 shows that the mean ratio is 1.03 for CCPs, indicating that the net position with CCPs is close to zero. By comparison, the ratio is 5.77 for non-CCP counterparties, which shows that banks engage in one-directional trades with such counterparties.

To investigate the role of netting benefits formally we compute a proxy variable capturing netting opportunities between repo and reverse repo (as in Hempel et al. (2023)):

$$\text{netting}_{i,j} = \frac{2 \times \min \left( \sum_t \text{repo}_{i,j,t}, \sum_t \text{revrepo}_{i,j,t} \right)}{\sum_t \text{repo}_{i,j,t} + \text{revrepo}_{i,j,t}}. \quad (6)$$

A value closer to 1 is indicative of higher netting benefits and we expect the subsample of transactions with CCP counterparties to have higher values of the proxy variable. Table 14 shows that the mean of the variable is higher for the subsample of CCP counterparties. In addition, the distribution is more tilted towards larger values than in the subsample of non-CCP counterparties. This is also confirmed by a comparison of the distributions of these measures across the two counterparty types in Figure OA.1 of the Online Appendix,

although the two subsamples have very different sizes.

We analyze the netting benefit hypothesis formally in Table 15 by reporting tests of differences in means between the two subsamples. The null hypothesis is equality of means against a two-sided alternative in the first two rows, and against the alternative of a larger mean of the netting proxy for CCP counterparties in the last two rows. In both cases, we consider a version of the test assuming equal variance in the two subsamples and one version where equal variance is not assumed. The results indicate that the mean of the netting variable is significantly different across the two subsamples, and significantly larger when CCPs act as counterparties.

Next, we study whether the probability of zero haircuts is statistically different for CCP trades. To control for collateral-level heterogeneity, we examine whether at the contract level, the probability of zero repo and reverse repo haircuts is different depending on whether the bank trades with a CCP or non-CCP counterparty. We run the following linear probability model:

$$D_j^{zero\ haircut} = \beta \times D_{j,CCP} + \gamma_1 \times notional_j + \gamma_2 \times maturity_j + CollateralFE + BankFE + \varepsilon_j, \quad (7)$$

where  $D_{j,CCP}$  takes the value 1 when the counterparty is a CCP.

The results are reported in Table 16. They show that the probability of a zero haircut rises by about 17% when the reporting banks lend via CCPs relative to lending to non-CCP counterparties, but this probability is lower for transactions with large notional values.<sup>24</sup> The estimates on maturity show that longer-maturity trades are less likely to have zero haircut. By comparison, for repo trades, whether the counterparty is a CCP or not does not affect the probability of a zero haircut.

Finally, we investigate the determinants of trading with a CCP. To do so, we run the following linear probability model:

$$D_{j,CCP} = \beta \times determinants_j + BankFE + \varepsilon_j. \quad (8)$$

Table 17 shows that the probability of a trade with a CCP is greatly increased (by 40–43%) when the netting proxy is equal to one – that is, netting benefits seem to be one of the main drivers of CCP trades.

Additionally, the probability of trading with a CCP in Table 17 increases in the notional

---

<sup>24</sup>This might also reflect the possibility that assets of low notional values are packaged in a collateral portfolio together with those of large notional values to back repo transactions. Therefore, haircuts are assessed on assets of large notional values to meet the initial margin requirement.

of the trade, in the collateral rating, and when the transaction is denominated in GBP, EUR and USD. Instead, the probability decreases for corporate and securitised debt collaterals.<sup>25</sup> Furthermore, government bonds used as collateral in trades with CCP counterparties tend to exhibit higher rehypothecation rates than comparable assets used in trades with non-CCP counterparties (see Table 4 and Table OA.VII of the Online Appendix).

Overall, we find that transaction with CCPs: (i) are characterized by higher quality collateral; (ii) are incentivized by the netting benefits that they entail for our reporting banks; (iii) are mostly associated with a *specific* collateral (at least in the SMMD dataset); (iv) are associated with a lower intermediation spread for the reporting banks, despite having a higher probability of zero haircuts; (v) tend to have larger notional amounts.

## 4.5 The pecking order of collateral choice

So far we have presented evidence that is in line with the predictions of an asymmetric information view of haircuts. A key ingredient of such models is the existence of information frictions between borrowers and lenders. The classical pecking order theory proposed by Myers (1984) and Myers and Majluf (1984), motivated by the adverse selection friction, suggests a hierarchical financing strategy. That is, to minimize the costs of borrowing, the source of capital with the lowest degree of information asymmetry should be used first when raising funds. In the repo setting this predicts that collateral of the highest quality should be used first by repo borrowers.

Even though our dataset is based on a single snapshot, we observe trades initiated at different dates that allow us to test for a pecking order. For instance, for borrowing maturing at time  $T$ , we observe collateral posted in transactions initiated in period  $T - 1$ ,  $T - 2$  etc. Hence, we can test whether there is a systematic pattern in the quality of collateral used over time.

To test the pecking order hypothesis we first compute, for each bank-counterparty pair  $(i, j)$ , the weighted average of the collateral quality backing borrowing in month  $t$  which will mature in month  $T$ , with  $T \geq 2$ .<sup>26</sup> We use the notation  $\text{CollRating}_{i,j,t}^T$  to denote this measure. We then compare this measure with the corresponding average collateral quality backing new borrowing in the following months  $(t + 1, t + 2, \dots)$  for *the same maturity date*, denoted

---

<sup>25</sup>A caveat of this analysis is that CCPs in our sample period did not experience stress. For an analysis of CCPs in turbulent times, see Duffie (2014) and Boissel et al. (2017).

<sup>26</sup>Recall that the numerical classification for collateral quality is on a scale from 1 to 20, with lower values representing lower collateral quality.

CollRating $_{i,j,t+k}^T$  in the following regression:<sup>27</sup>

$$\text{CollRating}_{i,j,t+k}^T = \beta_0 \times \text{CollRating}_{i,j,t}^T + \text{controls} + \text{FEs} + \varepsilon_{i,j,t+k}, \forall k \in [1, T - t] \quad (9)$$

where  $\beta_0$  is the coefficient of interest. If there is no pecking order in the posting of collateral, we would expect the average collateral quality to be similar at different points in time, hence we would expect  $\beta_0 = 1$ . Instead if, for a given borrowing maturity, higher quality collateral tends to be posted first, we would expect  $\beta_0 < 1$ . We include the borrowing horizon, the initial amount borrowed and the time difference between the initial and new borrowing ( $k$ ) as control variables. We consider different combinations of reporting banks, counterparty sector and time fixed effects. The standard errors are clustered at the counterparty and time level in all the cases.

Table 18 shows our estimation results for equation 9.<sup>28</sup> In addition, each row of Table 19 reports the 95% confidence interval around the estimate of our coefficient of interest for the corresponding column. In all specifications, the coefficient estimates are significantly smaller than one at canonical confidence levels. That is, counterparties of our reporting banks seem to choose high quality collateral first when borrowing via repo contracts.

Overall, we interpret the findings on a pecking order in collateral selection as evidence of an information friction channel being at play in the repo market. Nevertheless, in Myers (1984) and Myers and Majluf (1984), a pecking order arises due to a very specific form of information friction: adverse selection. Hence, we now turn to testing for this friction directly.

In particular, we test whether reporting banks apply different haircuts on their lending depending on the counterparty type, controlling for other relevant characteristics of the transaction. That is, we consider the specification:

$$\begin{aligned} \text{Haircut}_j = & \gamma \times \text{sophisticated} + \beta \times \text{determinants}_j + \text{BankFE} \\ & + \text{CollFE} + \text{TradeDateFE} + \text{RelationshipFE} + \text{CurrencyFE} + \varepsilon_j, \end{aligned} \quad (10)$$

where *sophisticated* is a dummy variable taking a value of 1 if the counterparty is another reporting bank, broker-dealer, hedge fund or other asset manager. Compared to our baseline specification, we add collateral and trade date fixed effects to compare the haircuts between

---

<sup>27</sup>In the analysis, we focus on the transactions reported during 2012, where most of the observations are concentrated. We aggregate the transactions taking place within the same month between a bank-counterparty pair to compute the variables entering our regression. Setting  $t = 1$  in January 2012, we have  $k \in [1, 11]$  and  $T > k$ .

<sup>28</sup>The final sample contains 327 observations between 81 unique clients and the 6 reporting banks.

two transactions on the *same trade date* with the *same reporting bank* and backed by the *same collateral*. We therefore expect the parameter  $\gamma$  to capture the additional haircut applied by the reporting bank as a buffer against potential information advantage and/or unobservable risk-taking of more sophisticated counterparties, controlling for other relevant determinants of the transaction and of the counterparty risk profile.

Regression results are reported in Table 20. The first 2 columns include only the sophistication dummy as regressor and show that more sophisticated counterparties are charged between 2.4 and 3.5 pp higher haircuts for borrowing backed by the same collateral, obtained from the same bank on the same trade date. The addition of the relationship fixed effects in the second column does not impact the result, and increases the magnitude of the estimate. The last column confirms that the sophistication dummy remains significant when considered jointly with the other explanatory variables. This implies that the data supports the adverse selection channel as a driver of haircuts.

## 4.6 The link between repo interest rates and haircuts

Despite its richness in terms of repo deal information, our baseline dataset does not contain the repo rates applied to the individual contracts. This is potentially problematic since demanding higher haircuts could be to some extent a substitute for offering lower interest rates. To check whether this issue might be at play, we complement our analysis with the Bank of England Sterling Money Market daily (SMMD) dataset. The SMMD data contains transaction-level information, including haircuts and deal rates, for which GBP denominated repos are secured against UK government bills and bonds (nominal and index-linked Gilts). Hence, in this dataset, we have no rating heterogeneity but the collateral quality is captured by its maturity, whether it is inflation linked or not, since the two market segments have quite different liquidity, and VaR of the asset.

In Table 21 we regress haircuts on these collateral quality proxies, deal characteristics, and importantly the rate spread relative to the central bank base rate. In a naïve regression of haircuts on only the deal rate in columns (1) and (2), we do indeed find a statistically significant link between the two variables (albeit the sign is the opposite of what a substitutability between the two would predict). Nevertheless, the simple addition of counterparty fixed effects, in column (3), or just controlling for the quality of the collateral, in columns (4) to (6) with or without fixed effects, make the rate irrelevant in explaining haircuts. Furthermore, when controlling for time fixed effects – hence for the overall credit condition on a given date – the coefficient associated with the repo rate is not only statistically indistinguishable from, but also very close to, zero.

This finding could *prima facie* look surprising, but it is in line with several findings in the existing literature. For example, Eisenschmidt et al. (2024) (see table 3 therein) find no statistical association between rates and haircuts in the Money Market Statistical Reporting (MMSR) European repo dataset from the ECB. In the same vein, in Hempel et al. (2023) the average repo rates across collateral categories do not appear to be statistically different (see Figure 5 therein). On the contrary, Weymuller (2013), using tri-party repo transactions of one large U.S. money market fund over the 2006-2012 period, finds (in an untabulated regression) a statistically significant link between rates and haircuts. However, his specification has a very limited set of controls compared to our analysis, and that might drive his finding (as in columns (1) and (2) of Table 21, where we omit salient control variables). But obviously, since the SMMD database is characterized by overall less risky collateral than our baseline dataset, it is still conceivable that riskier asset classes might have both greater haircuts and higher rates.

This finding suggests that haircuts and repo rates have different drivers. A potential explanation is that repo rates are determined by the market makers to clear *aggregate* demand and supply of funds, while haircuts instead are determined at the *contract level* based on risk considerations. This explanation is in line with anecdotal evidence we have collected interviewing directly the credit officers and market makers of the repo desks at the reporting banks in our baseline dataset. The reason for this pooling of collateral (with different haircuts) in the determination of the overall repo rate is driven by liquidity considerations in market practice, as it would be costly to clear demand and supply of funds in collateral- and counterparty-specific markets.<sup>29</sup>

Hence, the absence of an empirical link between rates and haircuts of repo contracts alleviates concerns of our baseline analysis being affected by an omitted variable due to excluding repo rates.

## 5 Conclusion

In this study, we analyze the structure of the UK bilateral repo market using a unique transaction-level dataset. We uncover features of the repo market in the UK that are distinct from the U.S. market. In this unique setting, we examine how banks intermediate liquidity among different counterparties via repo trades and how they use CCPs to borrow and lend against higher quality collateral and exploit netting benefits.

We examine the characteristics of contract terms including maturity structure, collateral

---

<sup>29</sup>Note also that in tri-party repo markets haircuts are actually fixed in the custodian agreements, that are revised infrequently, while the rates are determined at higher frequency to clear demand and supply of funds.

and counterparty types associated with these trades and test various economic mechanisms that can affect the amount of repo liquidity provided via haircuts. Besides asset quality and liquidity, we find that quality and sophistication of borrowing counterparties matter in haircut determination. We do not find that lenders' liquidity position or default probabilities affect the size of haircuts. Furthermore, we observe a pecking order in the posting of collateral, with the higher quality ones used first when borrowing.

# Figures

Figure 1: Currency vs. maturity of the contracts

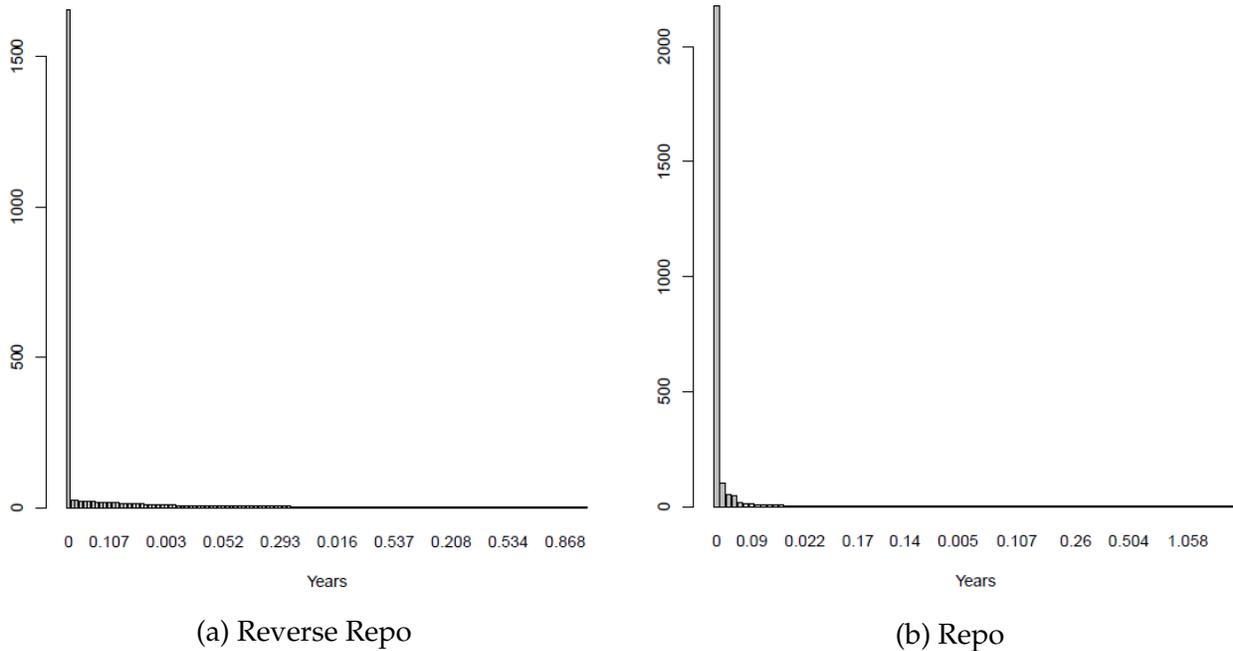

The area of each rectangle represents the fraction of contracts (in terms of frequency, not notional values) within a particular maturity-currency group. The area of the entire square is 100%.

Figure 2: Distribution of haircuts

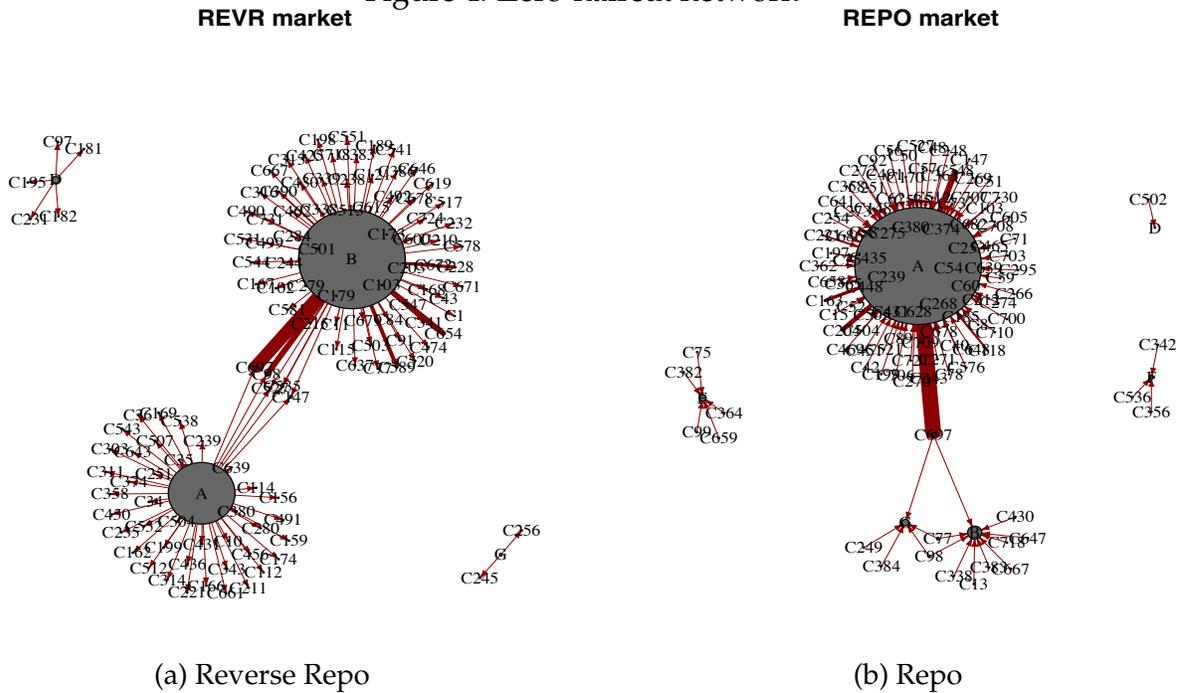

The figure shows the density of haircuts for both Repo and Reverse Repo contracts.

Figure 3: Maturity distribution of zero-haircut deals

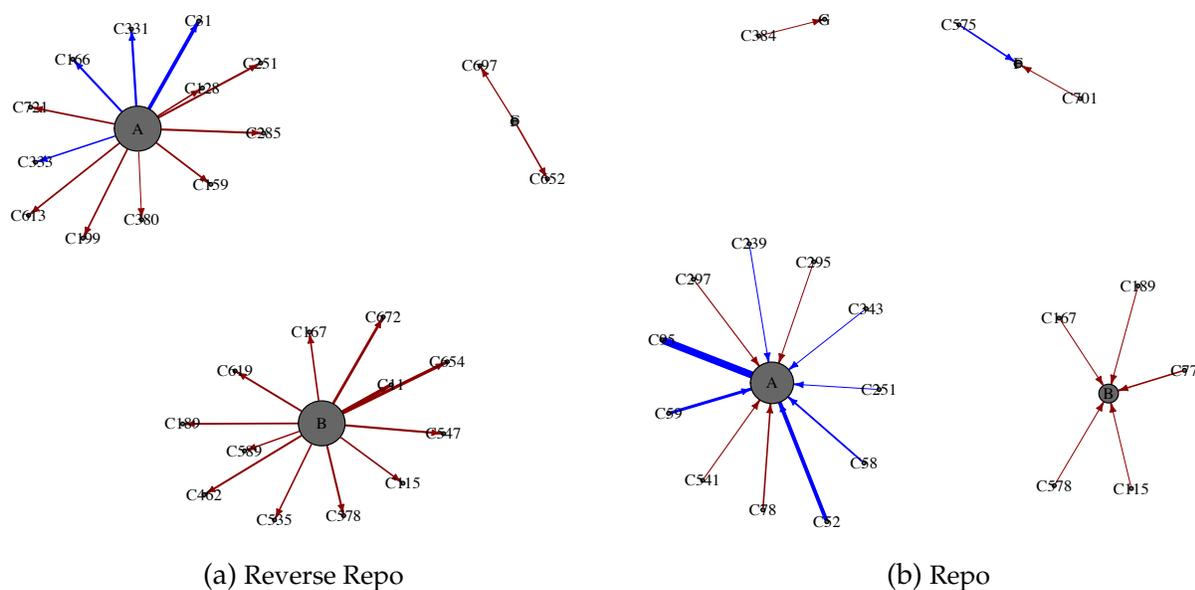

Number of zero-haircut contracts for each maturity in the zero-haircut subsample.

Figure 4: Zero-haircut network

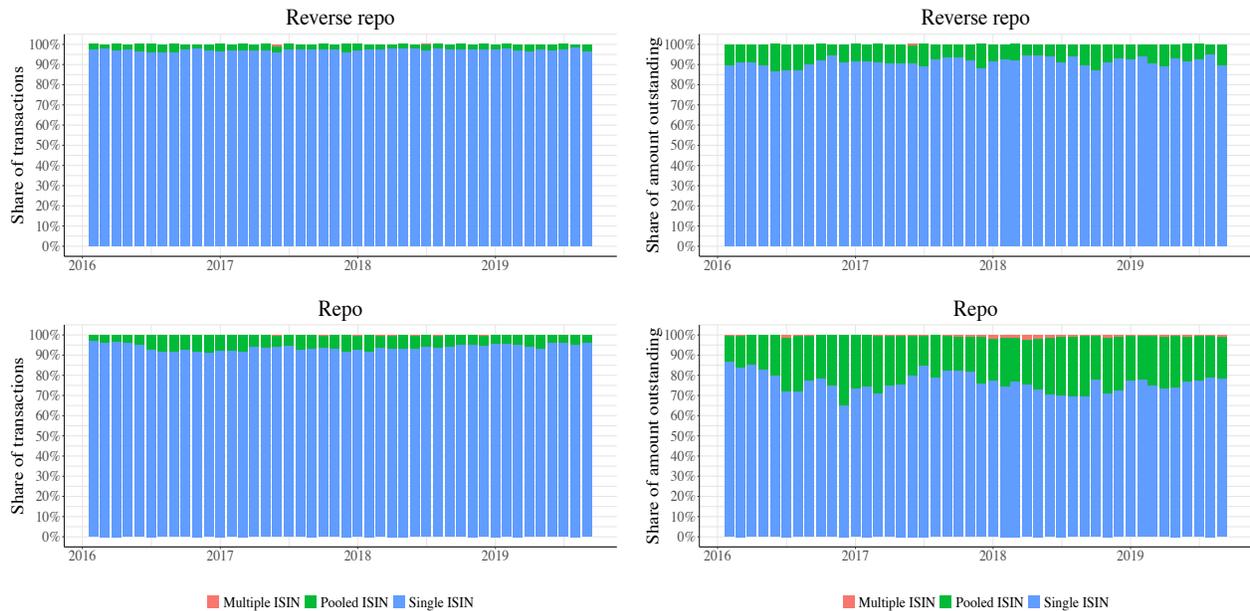

The size of each node reflects the number of counterparties with which it has at least one zero-haircut deal. Edge width is increasing in the total number of zero-haircut trades between two given nodes. A, B, D, E, F, and G denote the six reporting banks, and nodes labeled with C and numeric denote their counterparties.

Figure 5: Significant relationship fixed effects  
**REVR market** **REPO market**

Network graph implied by the statistically significant, at the 5% (one sided) level, relationship fixed effects for reverse repo (panel (a)) and repo (panel (b)) contracts. Estimates based on the regressions from columns 5 (reverse repo) and 10 (repo) of Table 8. A relationship is defined as having at least 10 bilateral transactions. Red (blue) arrows denote negative (positive) fixed effects while their direction represents the lending flow. Node sizes are proportional to the number of bilateral relationship fixed effects involving the given node. Edge width is increasing in the absolute magnitude of the estimate. A, B, D, E, F, and G denote the six reporting banks, and nodes labeled with C and numeric denote their counterparties.

Figure 6: Breakdown of transaction types for trades with CCP counterparties.

(a) Share of transactions

(b) Value-weighted share of transactions

This figure shows the monthly average shares of daily outstanding reverse repo (upper panels) and repo transactions (lower panels) between the reporting banks and CCPs by collateral categories. Left panels report raw shares while right panels report the corresponding value-weighted values. “Single ISIN” corresponds to transactions for which the security used for collateral can be identified by a single ISIN code. “Multiple ISIN” corresponds to transactions for which the securities used as collateral can all be identified by single ISIN codes. “Pooled ISIN” corresponds to transactions for which the eligible collateral is represented by a pool or basket of securities. Each category is expressed as a percentage of the monthly average total of outstanding transactions. The sample period ranges from 2016 to 2019.

Overall average	1.2%	0.7%		

The table presents the breakdown of the deals by maturity, currency, counterparty type, and collateral type (Panels A, B, C, and D, respectively). For each category, it shows the average haircut (columns 2 and 3), as well as the distribution of zero haircut deals (columns 4 and 5), for the reverse repos and repos, respectively. The averages are weighted by the gross notional of the transactions. The haircuts are based on the data from the six banks that report haircut and collateral information (excluding deals with CCPs).

<sup>a</sup> The reporting banks report on a UK-consolidated basis, but counterparties are reported on a global basis. Therefore, there may be discrepancies between the reverse repos and repos with the reporting banks.

<sup>b</sup> Broker-dealers are mostly securities firms that are subsidiaries of large banks. <sup>c</sup> Non-leveraged non-MMF mutual funds—asset managers that are not hedge fund or MMF. <sup>d</sup> Includes corporations, schools, hospitals and other non-profit organizations. <sup>e</sup> Greece, Italy, Ireland, Portugal, and Spain government bonds.

The table shows the summary statistics of variables used in the regressions excluding the deals with CCPs, for repo and reverse repo transactions. The sample only includes the six banks that provided data on haircuts and collateral. Variables have been winsorized at 0.5% level. Rating scale is 1–20, with 20 being the highest rating.

<sup>a</sup> Average is weighted by the gross notional of transactions.

The table shows the summary statistics of variables used in the regressions excluding the deals with CCPs, for repo and reverse repo transactions across the subsamples of a) government securities with AA+ and above rating, b) government securities with ratings smaller or equal to A, and c) other securities. Variables have been winsorized at 0.5% level for each category of collateral. Rating scale is 1–20, with 20 being the highest rating. Average is weighted by the gross notional of transactions.

OLS regressions (equation (3)) for reverse repo, columns (1)-(5), and repo, columns (6)-(10), excluding deals with CCPs. The dependent variable is haircut and explanatory variables are listed in the first column. All quantitative variables (notional, maturity, collmaturity, VaR, cptysize, cptyroa, cptyleverage, cptycnds, cptycashratio, cptycon, collcon) are standardized. All regressions include bank, relationship, and currency fixed effects. Standard errors are clustered at the counterparty level.

\*  $p < 0.1$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$ .

OLS regressions for the reverse repo subsamples excluding deals with CCPs (equation (4)). The dependent variable is haircut and explanatory variables are listed in the first column. Columns (1)-(5) capture the baseline—corresponding to highly-rated government securities—effects, while columns (6)-(10) and (11)-(15) capture the marginal effects, respectively, of lower-rated government securities and other collaterals. All quantitative variables (notional, maturity, collmaturity, VaR, cptysize, cptyroa, cptyleverage, cptycds, cptycashratio, cptycon, collcon) are standardized. All regressions include bank, relationship, and currency fixed effects. Standard errors are clustered at the counterparty level.

10%	40.3%	-7.5	9.0%	44.8%	-9.9	22.4%
5%	32.8%	-7.9	6.0%	43.3%	-10.1	17.9%
<b>Panel B: Repo</b>						
10%	27.9%	-3.9	23.3%	55.8%	-5.4	25.6%
5%	25.6%	-4.1	18.6%	51.2%	-5.8	23.3%

The table reports the share of significantly negative and positive relationship fixed effects for different significance levels reported in the first column, for a specification with (columns two to four) and without (columns five to seven) reporting bank fixed effects. The specification with bank fixed effects is from columns 5 and 10 of Table 8, whereas the specification without is based on the same regressions but excluding bank FEs. The conditional means (columns three and six) are the average of the significantly negative fixed effects.

OLS regressions for the reverse repo subsamples excluding deals with CCPs (equation (9)). The dependent variable is the average collateral quality backing new borrowing for the same maturity date as the initial transaction. Explanatory variables are listed in the first column and include the average collateral quality backing initial borrowing (our variable of interest), the maturity and total notional amount borrowed initially, and the time difference between initial and new borrowing ( $k$ ). Columns (1)-(7) consider different combinations of bank, counterparty sector, and time fixed effects. Standard errors are clustered at the counterparty and time levels, and reported below the coefficient estimates between parentheses.

Table 19: 95% confidence intervals around pecking order coefficient estimates

Specification	2.5 %	97.5 %
No FEs	0.559	0.759

\*  $p < 0.1$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$

OLS regressions for the reverse repo subsamples of the SMMD data. The dependent variable is haircut and explanatory variables are listed in the first column. Columns (1)-(3) consider a baseline specification controlling only for the transaction spread relative to the central bank policy rate, and columns (4)-(6) add other control variables. In both cases, different combinations of bank, counterparty, and time fixed effects are considered. Standard errors are clustered at the bank and counterparty levels, and reported below the coefficient estimates between parentheses.

# Appendix

## A.1 A stylized model of Repo haircut determination

We present here a stylized model to motivate the testable hypotheses on haircut of repo loans. Consider an economy with two dates, date 0 and date 1 where all agents are risk neutral. There are agents who need funds for starting productive projects at date 0 with a deterministic gross return  $z > 1$  at date 1. There is also a representative lender with deep pockets. To overcome the limited commitment problem, the borrowers need to use the collateral asset to back the borrowing at date 0, that is, they use a form of repo loan.

We assume that the collateral asset yields a random payoff  $\tilde{\delta}$  at date 1.<sup>1</sup> The asset can be of high or low quality. The probability of low type is  $\lambda$ . Quality is i.i.d and privately known to the borrower. For expositional clarity, we derive the comparative statics using a two-point distribution. Specifically, the high (low) quality asset pays one unit of payoff with probability  $\pi_H$  ( $\pi_L$ ) and pays  $e \in (0, 1)$  otherwise, where  $0 \leq \pi_L < \pi_H \leq 1$ . We assume that, when the ownership of the collateral asset is transferred, a fraction  $\gamma \in (0, 1)$  of the asset value is destroyed (e.g., due to illiquidity, transaction cost or lost of convenience yield). To raise funds, borrowers can issue a security that promises to pay  $y$  and is backed by the collateral payoff. The debt contract takes a simple form. It pays  $y = \min\{d, (1 - \gamma)\tilde{\delta}\}$ . That is, in the case of default, the lender can only obtain a  $1 - \gamma$  fraction of the collateral value, and receive the face value of debt contract ( $d$ ) otherwise.

Next, we discuss the market microstructure. We assume that the lending market is competitive. The representative (risk neutral) lender, hence, earns zero profit. The cost of lending for the representative lender is normalized to 1. There are gains from trade since  $z > 1$ . We also assume that the gains from trade parameter is small enough, that is,  $z < 1/(1 - \lambda)$  so that it will not make the impact of the information friction irrelevant in this model. Furthermore, the collateral price  $\phi$  is set as  $\phi = \mathbb{E}\{\tilde{\delta}\}$  due to the risk neutral assumption. The amount of lending offered by the lender is the price of the loan contract, which is denoted by  $q$ . The haircut is, hence, defined as  $h = 1 - q/\phi$ .

This is a model of lemons since the borrowers with the low quality collateral always issue asset-backed securities to raise fund in order to access a return of  $z$ . The borrowers with the high quality collaterals, however, might not participate since their asset-backed security would be pooled with the low quality borrowers and priced at a lower value. Hence, the

---

<sup>1</sup>We denote random variable with  $\tilde{\cdot}$ .

participation constraint is

$$z\mathbb{E}\{y\} = z(\lambda\mathbb{E}_L\{y\} + (1 - \lambda)\mathbb{E}_H\{y\}) \geq \mathbb{E}_H\{y\} \quad (\text{A.11})$$

where the left side of the inequality is the payoff from issuing an security priced at the pooling price and investing in the project with return  $z$ , and the right side of the inequality is the payoff from holding onto the collateral.

Note that in this stylised model quality of the borrower and quality of the collateral are isomorphic. That is, we bundle together two information frictions: the adverse selection with respect to both borrower default risk and the credit quality of the posted collateral.

Next, we define the information sensitivity ratio of a security issued by the borrowers in this economy, denoted by  $\zeta(y) \equiv \mathbb{E}_L\{y\}/\mathbb{E}_H\{y\}$ . The smaller is  $\zeta(y)$ , the more there is a difference in payoffs of high and low collaterals, and the more information sensitive is the security's payoff, which in turn leads to more adverse selection. When condition (A.11) holds with equality, we obtain a threshold  $\bar{\zeta}$  which is the lowest possible information sensitivity ratio of a security that the borrowers with high quality collaterals are willing to issue knowing that they will be pooled with the borrowers with low quality collaterals.

$$\zeta(y) \equiv \frac{\mathbb{E}_L\{y\}}{\mathbb{E}_H\{y\}} \geq 1 - \frac{z-1}{z\lambda} \equiv \bar{\zeta} \quad (\text{A.12})$$

where  $\bar{\zeta}$  measures the adverse selection level of the lemon market. It is decreasing in the productivity parameter  $z$  and increasing in the probability of low type,  $\lambda$ .

The information sensitivity ratio of the repo debt is

$$\zeta\{d, \tilde{\delta}\} = \frac{\mathbb{E}_L \min\{d, (1 - \gamma)\tilde{\delta}\}}{\mathbb{E}_H \min\{d, (1 - \gamma)\tilde{\delta}\}}. \quad (\text{A.13})$$

We assume that parameters  $\pi_L, \pi_H, e$  are such that  $\zeta\{1, \tilde{\delta}\} < \bar{\zeta}$  to ensure that the information friction is severe enough for the haircut problem to be non-trivial.

We are now ready to characterize the face value of the loan. We first obtain the price of the loan contract,  $q$ , which satisfies the following zero profit condition:

$$\begin{aligned} q &= \mathbb{E}\{\min\{d, (1 - \gamma)\tilde{\delta}\}\} \\ &= \mathbb{E}\{\tilde{\delta}\} - [\lambda\pi_L + (1 - \lambda)\pi_H](1 - d) - \gamma e[(1 - \pi_L)\lambda + (1 - \pi_H)(1 - \lambda)] \end{aligned} \quad (\text{A.14})$$

The indifference condition for the high type borrowers to participate in this market for

lemons is

$$\zeta\{d, \tilde{\delta}\} = \bar{\zeta}. \quad (\text{A.15})$$

We assume that lenders want to maximize the lending by setting the face value high enough to meet this indifference condition. Hence, the face value of the debt,  $d$ , can be obtained by solving equation (A.15), which is

$$d = (1 - \gamma)e \left( 1 + \frac{1 - \bar{\zeta}}{\bar{\zeta}\pi_H - \pi_L} \right). \quad (\text{A.16})$$

Combining equations (A.14) and (A.16), we obtain the haircut for repo loans,

$$h = \frac{1}{\phi} \left[ 1 - (1 - \gamma)e \left( 1 + \frac{1 - \bar{\zeta}}{\bar{\zeta}\pi_H - \pi_L} \right) \right] [\lambda\pi_L + (1 - \lambda)\pi_H] + \frac{\gamma}{\phi} e [(1 - \pi_L)\lambda + (1 - \pi_H)(1 - \lambda)] \quad (\text{A.17})$$

where  $\phi = \mathbb{E}\{\tilde{\delta}\}$ . Equation (A.17) shows that the repo loan haircut depends on the distribution parameter  $\pi_H - \pi_L$ , illiquidity  $\gamma$ , and adverse selection parameter  $\bar{\zeta}$ . We categorize these parameters into two types. One type is related to the risk of asset payoff such as  $(\pi_H - \pi_L)$  and illiquidity ( $\gamma$ ). The other type is related to adverse selection. The following results follow directly from (A.17).

**PROPOSITION 1:** Haircuts are larger for risky assets and illiquid assets.

Equation (A.17) also shows that the higher the adverse selection parameter  $\bar{\zeta}$ , the larger the haircut, which leads to the following result.

**PROPOSITION 2:** Haircuts are increasing in the degree of adverse selection.

Additionally, we find that the participation constraint is relaxed when the borrowing is backed by a portfolio of one unit of risky collateral and one unit of the safe asset that pays 1 unit irrespective of the state since

$$\zeta^{safe}(d, \tilde{\delta}) = \frac{1 + \mathbb{E}_L \min\{d, (1 - \gamma)\tilde{\delta}\}}{1 + \mathbb{E}_H \min\{d, (1 - \gamma)\tilde{\delta}\}} > \frac{\mathbb{E}_L \min\{d, (1 - \gamma)\tilde{\delta}\}}{\mathbb{E}_H \min\{d, (1 - \gamma)\tilde{\delta}\}}. \quad (\text{A.18})$$

Intuitively, the portfolio that combines safe with risky collaterals is less information sensitive. Therefore, the adverse selection is lower and the haircut on this portfolio is smaller.

**PROPOSITION 3:** Haircuts are lower when safe assets are included in the portfolio of collateral assets.

Table A.I: Description of the explanatory variables

Variable	Description
gbp	Dummy variable = 1 if transaction is in GBP.
eur	Dummy variable = 1 if transaction is in EUR.
jpy	Dummy variable = 1 if transaction is in JPY.
othercurrency	Dummy variable = 1 if transaction is not GBP, EUR or JPY.
notional	Log notional of the transaction in millions GBP.
maturity	Maturity of the transaction in years.
collrating	Rating of the collateral: 20 is highest and 1 is lowest.
collmaturity	Maturity of the collateral in years.
corpdebt	Dummy variable = 1 if collateral is corporate bond.
securitization	Dummy variable = 1 if collateral is securitisation.
VaR	Historical 5-day, 5% Value-at-Risk of the asset.
asset in safe portf	Dummy variable = 1 if the asset is in a portfolio with at least one asset rated AAA.
brokerdealers	Dummy variable = 1 if counterparty is a broker-dealer.
hedgefund	Dummy variable = 1 if counterparty is hedge fund.
otherassetmanagers	Dummy variable = 1 if counterparty is other asset managers.
insurance&pension	Dummy variable = 1 if counterparty is insurance company or pension fund.
centralbank&government	Dummy variable = 1 if counterparty is central bank or government.
other	Dummy variable = 1 if counterparty is other type.
cptysize	Log size of the counterparty in millions GBP.
cptyroa	RoA of the counterparty.
cptyrating	Rating of the counterparty: 20 is highest and 1 is lowest.
cptyleverage	Leverage ratio of the counterparty (RWA over equity).
cptycbs	CDS spread of the counterparty.
cptycashratio	Cash ratio of the counterparty (cash over short-term debt).
nocptydata	Dummy variable = 1 there is no counterparty data.
cptycon	Concentration of the counterparty measured by the share of transactions with that counterparty in total: higher number indicates more concentration.
collcon	Concentration of the collateral measured by the share of transactions against that collateral in total: higher number indicates more concentration.
cptyandcollrating	Interaction term between counterparty rating and collateral rating

Tobit regressions for reverse repo, columns (1)-(5), and repo, columns (6)-(10), excluding deals with CCPs. The dependent variable is haircut and explanatory variables are listed in the first column. All quantitative variables (notional, maturity, collmaturity, VaR, cptysize, cptyroa, cptyleverage, cptycnds, cptycashratio, cptycon, collcon) are standardized. All regressions include bank, relationship, and currency fixed effects. Standard errors are clustered at the counterparty level.

The table presents the breakdown of the deals by maturity, currency, counterparty type, and collateral type (Panels A, B, C, and D respectively) for the sample of six banks excluding CCPs. For each category, it shows the value of the trades in billions GBP and the percentage of total trades for the reverse repos and repos respectively. The total values in Panels A, B, C and D are based on the data from the six reporting banks that report haircut and collateral information. Discrepancies in row Total between the Panels are due to missing information.

<sup>a</sup> The reporting banks report on a UK-consolidated basis, but counterparties are reported on a global basis. Therefore there may be discrepancies between the reverse repos and repos with the reporting banks.

<sup>b</sup> Broker-dealers are mostly securities firms that are subsidiaries of large banks. <sup>c</sup> Non-leveraged non-MMF mutual funds—asset managers that are not hedge fund or MMF. <sup>d</sup> Includes corporations, schools, hospitals and other non-profit organizations. <sup>e</sup> Greece, Italy, Ireland, Portugal, and Spain government bonds.

This table exhibits a finer breakdown of the reverse repo contracts. The numbers are in percentage points and indicate the percentage of notional value in each category. The data is double sorted by counterparty type (columns) and maturity, currency and collateral type in Panels A, B, and C respectively. The table is based on the data from the six banks that report haircut and collateral information. Columns 1–8 refer to the following counterparty types:

1. Another reporting bank; 2. Other banks; 3. Broker-dealer; 4. Hedge fund; 5. Other asset managers; 6. Insurance and pension; 7. Central bank & govt; and 8. Other

This table exhibits a finer breakdown of the repo contracts. The numbers are in percentage points and indicate the percentage of notional value in each category. The data is double sorted by counterparty type (columns) and maturity, currency and collateral type in Panels A, B, and C respectively. The table is based on the data from the six banks that report haircut and collateral information. Columns 1–8 refer to the following counterparty types:

1. Another reporting bank; 2. Other banks; 3. Broker-dealer; 4. Hedge fund; 5. Other asset managers; 6. Insurance and pension; 7. Central bank & govt; and 8. Other

Table OA.VII: Rehypothecation Rate of Assets in CCP transactions

	<5Y	5-10Y	10-20Y	>20Y
Gov $\geq$ AA	34.1%	52.4%	49.3%	85.2%
Gov < AA	33.5%	6.3%	33.1%	0.0%
Other	0.0%			

Rehypothecation rates computed at the CUSIP/ISIN-level as the total amount of collateral asset posted (via repo) divided by the total amount received (via reverse repo).

Figure OA.1: Comparison of netting measure across CCP and non-CCP counterparties.
